## Update Assessment of Spotted Seatrout (Cynoscion nebulosus) in Louisiana Waters 2021 Report

## Executive Summary

Landings of spotted seatrout (SST) in Louisiana have remained below 5 million pounds per year in the most recent decade with the exceptions of 2011-2013 and 2016-2017. The 2014 and 2018-2020 recreational harvests were the lowest observed since 1990. The highest recreational harvest on record (over 8 million pounds) was observed in 2011. After the commercial net ban in 1997, when rod and reel gear became the only allowed method of spotted seatrout harvest, commercial landings declined significantly and account for less than $0.1 \%$ of annual landings in the most recent decade.

A statistical catch-at-age model is used in this stock assessment to describe the dynamics of the female portion of the Louisiana spotted seatrout stock. The assessment model forward projects
 annual abundance at age from estimates of abundance in the initial year of the time-series and recruitment estimates in subsequent years. The model is fit to the data with a maximum likelihood fitting criterion. Minimum data requirements are fishery catch-at-age and an index of abundance. Landings are taken from the Louisiana Department of Wildlife and Fisheries (LDWF) Recreational Creel Survey and Commercial Trip Ticket Programs, the National Marine Fisheries Service (NMFS) commercial statistical records, and the NMFS Marine Recreational Information Program (MRIP). Abundance indices are developed from the LDWF experimental marine gillnet survey. Age composition of fishery catches are estimated with age-length-keys derived from age samples of the fishery and a growth model.

In earlier assessments of the LA SST stock (West et al. 2011, West et al. 2014, West et al. 2019), targets and explicit limits of fishing were proposed to ensure future sustainability of the stock. The proposed limits of fishing were based on the history of the stock by requiring female spawning stock biomass not fall below the lowest level observed earlier in the fishery in which the stock demonstrated sustainability. Based on results of this assessment update, estimates of stock status relative to the proposed limits indicates the stock is currently overfished and undergoing overfishing. Management actions will be needed in order to prevent future overfishing and recover the stock from its current overfished condition.

## Summary of Changes from 2019 Assessment

Assessment model inputs have been updated through 2020. No changes have been made to the assessment model itself. Trends in basin-specific fishery landings, fishery-independent gill-net catch rates, and corresponding age compositions (2014-2020) have also been included this report (see Appendix 4).

## 1. Introduction

A statistical catch-at-age model is used in this stock assessment to describe the dynamics of the female portion of the Louisiana (LA) spotted seatrout Cynoscion nebulosus (SST) stock from 1982-2020. The assessment model forward projects annual abundance at age from estimates of abundance in the initial year of the time-series and recruitment estimates in subsequent years. The model is fit to the data with a maximum likelihood fitting criterion. Minimum data requirements are fishery catch-at-age and an index of abundance (IOA). Commercial landings values are taken from the Louisiana Department of Wildlife and Fisheries (LDWF) Trip Ticket Program and the National Marine Fisheries Service (NMFS) commercial statistical records. Recreational harvest estimates are obtained from the LDWF Recreational Creel Program (LA Creel) and the NMFS Marine Recreational Information Program (MRIP). Abundance indices are developed from the LDWF experimental marine gillnet survey. Age composition of fishery catches are estimated with age-length keys derived from age samples of the fishery (2002-2020) and a growth model (1982-2001).

### 1.1 Fishery Regulations

The LA SST fishery is governed by the LA State Legislature, the Wildlife and Fisheries Commission, and the Department of Wildlife and Fisheries. Current recreational regulations are a 12 -inch minimum length limit (MLL) and a 25 -fish per day creel limit, with the exception of south-west Louisiana (from the Texas border to the Mermentau River) that is currently managed with a 15 -fish daily creel limit with a 12 -inch MLL and no more than two fish allowed over 25 -inches. Commercial harvest is limited to rod and reel gear only, with a 14 -inch MLL. Historic commercial and recreational SST fishery regulations were reviewed in an earlier assessment report (West et al. 2011).

### 1.2 Trends in Harvest

Time-series of recreational and commercial landings are presented (Table 1, Figure 1). Louisiana spotted seatrout landings have remained below 5 million pounds per year in the most recent decade with the exceptions of 2011-2013 and 2016-2017. The 2014 and 2018-2020 recreational harvests were the lowest observed since 1990. The highest recreational harvest on record (>8 million pounds) was observed in 2011. After the commercial net ban in 1997, when rod and reel gear became the only allowed method of spotted seatrout harvest, commercial landings declined significantly and account for less than $0.1 \%$ of annual landings in the most recent decade.

## 2. Data Sources

### 2.1 Fishery Independent

The LDWF fishery-independent experimental marine gillnet survey is used in this assessment to develop abundance indices for use in the assessment model. Below is a brief description of this surveys methodology. Complete details can be found in LDWF (2018).

For sampling purposes, coastal Louisiana is currently divided into five LDWF coastal study areas (CSAs). Current CSA definitions are as follows: CSA 1 - Mississippi State line to South Pass of the Mississippi River (Pontchartrain Basin); CSA 3 - South Pass of the Mississippi River to Bayou Lafourche (Barataria Basin); CSA 5 - Bayou Lafourche to eastern shore of Atchafalaya Bay (Terrebonne Basin); CSA 6 - Eastern shore of Atchafalaya Bay to western shore of Freshwater Bayou Canal (Vermillion/Teche/Atchafalaya Basins); CSA 7 - western shore of Freshwater Bayou Canal to Texas State line (Mermentau/Calcasieu/Sabine Basins).

The LDWF Marine Fisheries Section conducts routine standardized sampling within each CSA as part of a long-term comprehensive monitoring program to collect life-history information and measure relative abundance/size distributions of recreationally and commercially important species. These include the experimental marine gillnet, trammel net, and bag seine surveys.

In this assessment, only the experimental marine gillnet survey is used. This survey has the highest spotted seatrout catch rates, frequency of occurrence, and precision when compared to the other LDWF FI surveys. The survey is conducted with standardized design. Hydrological and climatological measurements are taken with each biological sample, including water temperature, turbidity, conductivity and salinity. Survey gear is a 750 -foot monofilament gillnet comprised of five 150 -foot panels of 1.0 , $1.25,1.5,1.75$, and 2.0 -inch bar meshes.

Samples are taken by 'striking' the net. All captured SST are enumerated and a maximum of 30 randomly selected SST per mesh panel are collected for length measurements, gender determination, and maturity information. When more than 30 SST are captured per mesh panel, catch-at-size is derived as the product of total catch and proportional subsample-at-size.

The survey was conducted from 1986 to April 2013 at fixed sampling locations within each CSA. The 1.25 and 1.75 -inch bar mesh sizes were not included in the survey until 1988. In October of 2010, additional fixed stations were added to this survey allowing more spatial coverage within each CSA. Beginning in April 2013, the survey design was modified where sampling locations are now selected randomly from the established stations within each CSA (Figure 2).

### 2.2 Fishery Dependent

## Commercial

Commercial SST landings are taken from NMFS commercial statistical records (1982-1998; NMFS 2021a) and the LDWF Trip Ticket Program (1999-2020).

For aging purposes, annual landings are allocated into six-month seasons (i.e., January-June and JulyDecember). Because only limited seasonal landings data are available from earlier in the fishery, the monthly landings records that are available are pooled into time-periods of consistent regulation (19811996 and 1997-1998) to develop seasonal catch compositions. Starting in 1999, seasonal catches are taken directly from the LDWF Trip Ticket Program.

Size composition of commercial catches in each year and season are derived from LDWF sampling effort (pre-1997 and 2014-2020) and MRIP records (1997-2013). Pre-1997 size distributions are only available for a limited number of years (1986 and 1990-1992) during which time the commercial sector operated under different MLLs and used a wider variety of harvest methods. Therefore, the 1990-1992 data are combined to describe the size composition of commercial catches from 1987-1996 (i.e., primarily a net fishery with a 14 -inch MLL) and the 1986 data are used to describe the 1981-1986 commercial size compositions (i.e., primarily a net fishery with 10 and 12 -inch MLLs; Table 2). Seasonal size distributions of commercial catches are not available pre-1997; therefore, equivalent size composition is assumed for each six-month period. For years following the commercial net ban (i.e., 1997-present; only rod and reel harvest allowed with a 14 inch MLL), size composition of commercial catches are taken from MRIP records and the LDWF Biological Sampling Program (i.e., assuming equivalent vulnerability to rod and reel gear for both fisheries, but selecting only sizes $\geq 14$ inches total length; Table 3 ).

## Recreational

Recreational SST landings estimates are taken from the LDWF recreational creel survey (LA Creel; 20142020) and estimates hindcast to the historic MRIP time-series (1982-2013; details in Appendix 1). Consequently, the pre-2014 recreational harvest estimates used in this assessment differ from the LA estimates currently published by MRIP (https://www.st.nmfs.noaa.gov/recreational-fisheries/data-anddocumentation/queries/index). Furthermore, due to changes made to the MRIP Access Point Angler Intercept Survey (APAIS) in 2013 (see https://www.fisheries.noaa.gov/topic/recreational-fishing-data\#making-improvements) and the recent transition from the MRIP Coastal Household Telephone Survey to the new Fishing Effort Survey (FES; see https://www.fisheries.noaa.gov/recreational-fishing-data/types-recreational-fishing-surveys\#fishing-effort-survey), harvest estimates currently available from MRIP also differ from those used in earlier LA SST stock assessments (West et al. 2011,West et al. 2014).

For aging purposes, SST harvest and live release estimates are derived in six-month periods described in the previous section. Live releases are further delineated as legal or illegal with LA Creel and MRIP catch disposition codes.

Size composition of SST harvest estimates are derived from the LDWF Biological Sampling Program (2014-2020) and MRIP (1982-2013; prior to the APAIS and FES calibration changes) for each year and six-month season (Table 3); size composition of legal live releases is assumed equivalent. Statewide size compositions obtained from the LDWF Biological Sampling Program are derived by statistically weighting the CSA-specific size compositions by the corresponding recreational landings estimates.

Size composition of under-sized releases in each year and season is estimated by first assuming all illegal discards as $<12$ inches total length. Some catch, however, is in fact legal-sized, but coded as illegal due to catches greater than the creel limit. These catches ( $\sim 2 \%$ of LA angler trips per year, 2018-2020; LA Creel unpublished data) occur infrequently and are thus considered negligible for purposes of this assessment. Size composition of SST catches < 12 inches are pooled from the years prior to recreational MLL implementation and used as proxies of sublegal size composition after the 12 inch MLL was implemented in 1987.

## Bycatch

## Menhaden Reduction Fishery

Time series of incidental catch of SST from the LA menhaden reduction fishery have been developed from observations of retained and released SST CPUE (numbers per purse seine set) and annual effort estimates of the menhaden reduction fishery (LDWF 2020, see Appendix 2). The mean estimates of spotted seatrout bycatch in the most recent decade indicate very low levels of SST bycatch relative to the landings of the directed LA fisheries ( $0.07 \%$ in units of weight). Due to the negligible level of estimated SST bycatch relative to the landings of the LA directed fisheries, incidental SST catches of the LA menhaden reduction fishery are not considered further in this assessment.

## Shrimp Fishery

Bycatch has been characterized for the 2019-2020 inshore LA shrimp fishery (Cagle and West 2020; see Appendix 3). Incidental catches of SST were observed in this study. A time-series of annual LA inshore bycatch of SST in units of weight can be estimated as the product of the mean bycatch to shrimp sample ratio from the bycatch study, the annual inshore LA shrimp landings, and the proportion of SST observed in the catches of the bycatch study, under the assumption that estimates from the study are characteristic of the inshore fishery through time. While this assumption allows calculation of a time-series of bycatch,
the fishery has transformed and developed over time making this assumption unlikely. Nevertheless, a time-series of SST bycatch estimates are calculated, following the method outlined, for comparison to the SST landings of the directed LA fisheries (Figure 3). The estimates of annual SST bycatch from the LA inshore shrimp fishery in the most recent decade indicate relatively low levels of bycatch when compared to the landings of the directed LA fisheries ( $6.6 \%$ in units of weight).

The age and sex composition of the annual estimates of SST bycatch can be calculated from the size composition of SST bycatch observed in the study, the annual SST bycatch estimates in units of numbers (converted from weight using the mean weight of SST observed in the study), the estimated sex ratio at size (see 3. Life History Information), and an age-length-key. Since the majority of samples in the bycatch study occurred in the fall months, the ALK developed in this assessment to assign ages to landings based on size in the second half of the calendar year (July-December) is used for this purpose (Table 8; see 5 . Catch at Age Estimation). All SST bycatch from the inshore LA shrimp fishery are assumed to not survive.

The time-series of estimated SST bycatch from the LA inshore shrimp fishery, as numbers of females greater than age- 0 , along with the corresponding annual yield and age-specific mean weights are included in a sensitivity run of the assessment model (Table 4; see 6. Assessment Model).

## 3. Life History Information

### 3.1 Unit Stock Definition

Spotted seatrout occur in estuaries and nearshore coastal habitat along the Atlantic and Gulf coasts from Cape Cod, Massachusetts, to the Bay of Campeche, Mexico (GSMFC 2001). Most of the harvest, however, is taken in the Gulf of Mexico (GOM) with the largest recreational harvest occurring in LA waters.

Studies using mitochondrial DNA markers (Gold and Richardson 1998; Gold et al. 1999) have confirmed significant population substructuring across GOM SST populations. For the purpose of this assessment, the unit stock is defined as those female SST occurring in LA waters. This approach is consistent with the current statewide management strategy; although SST in south-west LA (from the Texas border to the Mermentau River) are managed with slightly different regulations (see 1.1 Fishery Regulations).

### 3.2 Morphometrics

Weight-length regressions for LA SST were developed by Wieting (1989). For the purpose of this assessment, only the female-specific relationship is used with weight calculated from size as:

$$
\begin{equation*}
W=1.17 \times 10^{-5}(F L)^{2.97} \tag{1}
\end{equation*}
$$

where W is whole weight in grams and FL is fork length in mm. Fish with only FL measurements available are converted to TL (and conversely) using a relationship provided by the Florida Fish and Wildlife Institute (personal communication from Joe O'Hop, July 2010) as:

$$
\begin{equation*}
T L=1.0008 \times F L+0.6306 \tag{2}
\end{equation*}
$$

where FL is in mm .

### 3.3 Growth

Spotted seatrout exhibit differences in growth between males and females, with larger SST being predominantly female (Wieting 1989). The growth model developed for female SST in the previous assessment (West et al. 2018) that accounts for decreasing growth rates with age (i.e., damped growth model; Porch et al. 2002) is used in this assessment. Total length-at-age is calculated with the damped growth model as:

$$
\begin{align*}
T L_{a} & =28.1 \times\left(1-e^{\beta-0.113(a-0.0373)}\right)  \tag{3}\\
& \beta=\frac{0.414}{0.329}\left(e^{-0.329 a}-e^{-0.329 \times 0.0373}\right)
\end{align*}
$$

where $T L_{a}$ is female TL-at-age in inches and years.

### 3.4 Sex Ratio

The probability of being female at a specific size is calculated with a logistic function developed in West et al. (2011) as:

$$
\begin{equation*}
P_{f e m, l}=\frac{1}{\left[1+e^{[-0.464(T L-10.9)}\right]} \tag{4}
\end{equation*}
$$

where $P_{\text {fem }, l}$ is the estimated proportion of females in 1 inch TL intervals. The minimum sex ratio-at-size is assumed as 50:50.

### 3.5 Fecundity/Maturity

Spotted seatrout are serial spawners where annual fecundity is seasonally indeterminate. To realistically estimate annual fecundity (total egg production), the number of eggs spawned per batch and the number of batches spawned per season must be known. Estimates from a recent LDWF fecundity study (LDWF unpublished data) suggests female fecundity-at-size and female weight-at-size are roughly equivalent. However, estimates from the recent study were hindered by low sample sizes due to the inherent difficulty obtaining samples of spawning fish in the proper condition which led to large estimates of error around the fecundity estimates precluding their use for assessment purposes. Therefore, female spawning
stock biomass (SSB) is used as a proxy for total egg production in this assessment. This may introduce bias if fecundity does not scale linearly with body weight (Rothschild and Fogarty 1989).

Female maturity at size is calculated with a logistic function developed in West et al. (2011) as:

$$
\begin{equation*}
P_{m a t, T L}=\frac{1}{\left[1+e^{[-0.765(T L-7.70)]}\right]} \tag{5}
\end{equation*}
$$

where $P_{\text {mat,TL }}$ is the estimated proportion of sexually mature female spotted seatrout in 1 inch TL intervals. Female maturity at age is then calculated by substituting equation [5] into equation [3].

### 3.6 Natural Mortality

Spotted seatrout can live to at least ten years of age (GSMFC 2001, Herdter et al. 2019). For purposes of this assessment, a value of average M is assumed (0.3) based on longevity of the species, but is allowed to vary with weight-at-age to calculate a declining natural mortality rate with age. This value of M is consistent with a stock where approximately $5 \%$ of the stock remains alive to 10 years of age (Quinn and Deriso 1999). Following SEDAR 12 (SEDAR 2006), the average value of $M$ is rescaled where the mean mortality rate over ages vulnerable to the fishery is equivalent to the average M rate as:

$$
\begin{equation*}
M_{a}=M \frac{n L(a)}{\sum_{a_{c}}^{a_{\max }} L(a)} \tag{6}
\end{equation*}
$$

where $M$ is the average natural mortality rate over exploitable ages $a, a_{\max }$ is the oldest age-class, $a_{c}$ is the first fully-exploited age-class, and $n$ is the number of exploitable ages. The Lorenzen curve as a function of age is calculated from:

$$
\begin{equation*}
L(a)=W_{a}^{-0.288} \tag{7}
\end{equation*}
$$

where -0.288 is the allometric exponent estimated for natural ecosystems (Lorenzen 1996) and $W_{a}$ is weight-at-age.

### 3.7 Discard Mortality

Reported SST discard mortality estimates are highly variable ( $\sim 5-95 \%$; Murphy et al. 1995; Stunz and McKee 2006; James et al. 2007; personal communication from Glenn Thomas, LDWF, July 2011). Results of these studies suggest the magnitude of post-release mortality as dependent on a number of factors including water quality, bait/hook type, anatomical hooking location, and angler skill-level. Spotted seatrout landings, however, are not directly separable into such components. Therefore, discard mortality is assumed constant in this assessment ( $10 \%$ ). This rate is consistent with the overall rod-andreel release mortality rates from the previously mentioned studies, i.e. $5,11,10$ and $14 \%$, respectively. For modeling purposes, stock losses due to discard mortalities are incorporated directly into recreational landings estimates (see 5. Catch at Age Estimation).

### 3.8 Winter Mortality

Spotted seatrout are subject to winter mortality events that vary with winter severity (Ellis et al. 2017). An index of winter severity was developed by compiling water temperature data from continuous water temperature monitoring stations across the LA coast and was calculated as the product of the number of days with water temperatures $\leq 7$ degrees Celsius (i.e., approximate water temperature SST cold-stun deaths begin to occur; Ellis et al. 2017) and the inverse of the mean water temperature during that duration (Table 5, Figure 4). Water temperature data from the months of November and December are grouped with the following year's January-March water temperatures for index development (e.g., winter of 1989-90 denoted as 1990).

### 3.9 Relative Productivity / Resilience

The key parameter in age-structured population dynamics models is the steepness parameter ( $h$ ) of the stock-recruitment relationship. Steepness is defined as the ratio of recruitment levels when the spawning stock is reduced to $20 \%$ of its unexploited level relative to the unexploited level and determines the degree of compensation in the population (Mace and Doonan 1988). Populations with higher steepness values are more resilient to perturbation and if the spawning stock is reduced to levels where recruitment is impaired are more likely to recover sooner once overfishing has ended. Generally, this parameter is difficult to estimate due to a lack of contrast in spawning stock size (i.e., data not available at both high and low levels of stock size) and is typically fixed or constrained during the model fitting process. Estimates of steepness are not available for spotted seatrout.

Productivity is a function of fecundity, growth rates, natural mortality, age of maturity, and longevity and can be a reasonable proxy for resilience. We characterize the relative productivity of LA SST based on life-history characteristics, following Southeast Data Assessment and Review (SEDAR) 9, with a classification scheme developed at the Food and Agriculture Organization of the United Nations (FAO) second technical consultation on the suitability of the Convention on International Trade in Endangered Species of Wild Fauna and Flora (CITES) criteria for listing commercially-exploited aquatic species (FAO 2001; Table 6). Each life history characteristic (von Bertalanffy growth rate*, age at maturity, longevity, and natural mortality rate) is assigned a rank (low $=1$, medium $=2$, and high $=3$ ) and then averaged to compute an overall productivity score. In this case, the overall productivity score is 2.75 for LA spotted seatrout indicating high productivity and resilience. The von Bertalanffy growth rate referenced above is replaced in this assessment with the mean growth rate across ages from the damped growth model weighted by expected relative abundance-at-age $(k=0.357)$.

## 4. Abundance Index Development

Abundance indices are developed separately for each mesh panel of the LDWF experimental marine gillnet survey with the exception of the 1.75 and 2.0 -inch bar meshes that are excluded due to low catch rates. Stations not sampled regularly through time (prior to October 2010) and the less frequent 'coldmonth' samples (i.e., October-March) are also excluded. Catch per unit effort is defined as the number of female SST caught in each mesh panel per net sample. To reduce unexplained variability in catch rates unrelated to changes in abundance, each IOA time-series was standardized using methods described below.

A delta lognormal approach (Lo et al. 1992; Ingram et al. 2010) is used to standardize female SST catchrates in each year as:

$$
I_{y}=c_{y} p_{y}
$$

where $c_{y}$ are estimated annual mean CPUEs of non-zero female SST catches assumed as lognormal distributions and $p_{y}$ are estimated annual mean probabilities of female SST capture assumed as binomial distributions. The lognormal and binomial means and their standard errors are estimated with generalized linear models as least square means and back transformed. The lognormal model considers only samples in which SST were captured; the binomial model considers all samples. Each IOA is then computed from equation [8] using the estimated least-squares means with variances calculated from:

$$
\begin{equation*}
V\left(I_{y}\right) \approx V\left(c_{y}\right) p_{y}^{2}+c_{y}^{2} V\left(p_{y}\right)+2 c_{y} p_{y} \operatorname{Cov}(c, p) \tag{9}
\end{equation*}
$$

where $\operatorname{Cov}(c, p) \approx \rho_{c, p}\left[\operatorname{SE}\left(c_{y}\right) \operatorname{SE}\left(p_{y}\right)\right]$ and $\rho_{c, p}$ represents the correlation of $c$ and $p$ among years.
Because of the designed nature of the experimental marine gillnet survey, model development was rather straightforward. Variables considered in model inclusion were year, CSA, and sampling location. Because only 'warm' month samples (i.e., April-September) are included, time of year was not considered in model inclusion. To determine the most appropriate models, we began the model selection process with a fully-reduced model that included only year as a fixed effect. More complex models were then developed including interactions and random effects and compared using AIC and log-likelihood values. All submodels were estimated with the SAS generalized linear mixed modeling procedure (PROC GLIMMIX; SAS 2008). In the final sub-models, year was considered a fixed effect, CSA was considered a random block effect, and sampling locations within CSAs were considered random subsampling block effects. Sample sizes, proportion positive samples, nominal CPUE, standardized indices, and coefficients of variation of the standardized indices are presented (Table 7). Standardized IOAs and nominal CPUEs, normalized to 1 for comparison, are also presented (Figure 5).

## 5. Catch at Age Estimation

Age-length-keys (ALKs) are developed to estimate the age composition of fishery and survey catches as described below.

Spotted seatrout in LA exhibit a protracted spawning season, with spawning primarily occurring across a six-month period from April through September (Hein and Shepard 1980). The mid-point of the spawning season (July $1^{\text {st }}$ ) is typically assumed as a biological birthday. However, for purposes of this assessment, ages were assigned based on the calendar year by assuming a January $1^{\text {st }}$ birthday, where SST spawned the previous year become age-1 on January $1^{\text {st }}$ and remain age-1 until the beginning of the following year.

### 5.1 Fishery

Beginning in 2002, ALKs are developed from age samples collected from the fishery. For earlier years, ALKs are developed from the damped growth model.

1982-2001 Probabilities of age $a$ given length $l$ in each six-month season ( $s$; January-June and JulyDecember) are computed as:

$$
\begin{equation*}
P(a \mid l)_{s}=\frac{P(l \mid a)_{s}}{\sum_{a} P(l \mid a)_{s}} \tag{10a}
\end{equation*}
$$

where the probability of length given age in each season is estimated from a normal probability density as:

$$
P(l \mid a)_{s}=\frac{1}{\sigma_{a s} \sqrt{2 \pi}} \int_{l-d}^{l+d} e\left[-\frac{\left(l-l_{a s}\right)^{2}}{2 \sigma_{a s}^{2}}\right] d l
$$

where length bins are 1 inch TL intervals with midpoint $l$, maximum $l+d$, and minimum $l-d$ lengths. Mean length-at-age in each season $l_{a s}$ is estimated from equation [3]. Variance in length-at-age is approximated as $\sigma_{a s}=l_{a s} C V_{l}$, where the coefficient of variation in length-at-age $C V_{l}$ is assumed constant (in this case 0.05 ). To approximate changes in growth during each season, mean length-at-age is calculated at the midpoint of each six-month period. Thus, two seasonal $P(a \mid l)_{s}$ matrices are developed to assign ages to female SST fishery landings from 1982-2001 (Table 8) and also for instances discussed below.

2002-2020 Probabilities of age given length for each year and six-month season are computed as:

$$
\begin{equation*}
P(a \mid l)_{y f s}=\frac{n_{\text {lays }}}{\sum_{a} n_{\text {lays }}} \tag{11}
\end{equation*}
$$

where $n_{\text {lays }}$ is female sample-size in each length/age bin in each year and six-month season (Table 10). When $\sum_{a} n_{\text {lays }}<10$, the $P(a \mid l)$ for that 1 inch TL interval is estimated with Equation [10].

Annual fishery-specific ( $f$, recreational or commercial) catch-at-age (females only) is then calculated as:

$$
\begin{equation*}
C_{a f y}=\sum_{l} \sum_{s} P_{f e m, l} C_{l f y s} P(a \mid l)_{y s} \tag{12}
\end{equation*}
$$

where $P_{f e m, l}$ is taken from equation [4], $C_{l f y}$ is fishery-specific catch-at-size in each year and six-month season, and $P(a \mid l)_{y}$ are taken from Equations [10 or 11]. Recreational discard mortalities are incorporated directly into the recreational harvest-at-age by applying a $10 \%$ discard mortality rate to the estimated recreational releases-at-size and combining them with the recreational harvest-at-size estimates. Resulting fleet-specific annual catch-at-age (including discard mortalities) and associated mean weights-at-age are presented (Tables 12-14).

### 5.2 Survey

Probabilities of age given length for female SST catches of the LDWF marine gillnet survey are computed from equation [10]. Mean length-at-age is estimated from equation [3]. Variance in length-atage is approximated as $\sigma_{a s}=l_{a s} C V_{l}$, where the coefficient of variation in length-at-age $C V_{l}$ is assumed constant (in this case 0.05). To approximate changes in growth during the survey period (AprilSeptember), mean length-at-age is calculated at the midpoint of the six-month survey period. Resulting survey $P(a \mid l)$ is presented (Table 9). Annual survey female catch-at-age is then taken from equation [12] with annual gear-specific survey catch-at-size substituted. Resulting annual survey age compositions (females only) are presented (Table 11, Figure 5).

## 6. Assessment Model

The Age-Structured Assessment Program (ASAP3 Version 3.0.12; NOAA Fisheries Toolbox) is used in this assessment to describe the dynamics of the female proportion of the LA SST stock. ASAP is a statistical catch-at-age model that allows internal estimation of a Beverton-Holt stock recruitment relationship and MSY-related reference points. Minimum data requirements are fishery catch-at-age, corresponding mean weights-at-age, and an index of abundance. ASAP projects abundance at age from estimates of abundance in the initial year of the time-series and recruitment estimates in subsequent years. The model is fit to the data with a maximum likelihood fitting criterion. An overview of the basic model configuration, equations, and their estimation, as applied in this assessment, are provided below. Specific details and full capabilities of ASAP can be found in the technical documentation (ASAP3; NOAA Fisheries Toolbox)

### 6.1 Model Configuration

For purposes of this assessment, the model is configured with annual time-steps (1982-2020) and a calendar year time-frame.

## Mortality

Fishing mortality is assumed separable by age $a$, year $y$, and fishery $f$ as:

$$
\begin{equation*}
F_{a y f}=v_{a f} F m u l t_{y f} \tag{13}
\end{equation*}
$$

where $v_{a f}$ are age and fishery-specific selectivities and Fmult $_{y f}$ are annual fishery-specific apical fishing mortality rates. Apical fishing mortalities are estimated in the initial year and as deviations from the initial estimates in subsequent years.

Fishery-specific selectivities are modeled with double logistic functions as:

$$
\begin{equation*}
v_{a f}=\left(\frac{1}{1+e^{-\left(a-\alpha_{f}\right) / \beta_{f}}}\right)\left(1-\frac{1}{1+e^{-\left(a-\alpha 2_{f}\right) / \beta 2_{f}}}\right) \tag{14}
\end{equation*}
$$

Total mortality for each age and year is estimated from the age-specific natural mortality rate $M_{a}$ and the estimated fishing mortalities as:

$$
\begin{equation*}
Z_{a y}=M_{a}+\sum_{f} F_{a y f} \tag{15}
\end{equation*}
$$

For reporting purposes, annual fishing mortalities are averaged by weighting by population numbers at age as:

$$
\begin{equation*}
F_{y}=\frac{\sum_{a} F_{a y} N_{a y}}{\sum_{a} N_{a y}} \tag{16}
\end{equation*}
$$

## Abundance

Abundance in the initial year of the time series and recruitment in subsequent years are estimated and used to forward calculate the remaining numbers at age from the age and year-specific total mortality rates as:

$$
\begin{equation*}
N_{a y}=N_{a-1, y-1} e^{-Z_{a-1, y-1}} \tag{17}
\end{equation*}
$$

Numbers in the plus group $A$ are calculated from:

$$
\begin{equation*}
N_{A y}=N_{A-1, y-1} e^{-Z_{A-1, y-1}}+N_{A, y-1} e^{-Z_{A, t-1}} \tag{18}
\end{equation*}
$$

## Stock Recruitment

Expected recruitment is calculated from the Beverton-Holt stock recruitment relationship, reparameterized by Mace and Doonan (1988), with annual lognormal deviations as:

$$
\begin{equation*}
\hat{R}_{y+1}=\frac{\alpha S S B_{y}}{\beta+S S B_{y}}+e^{\delta_{y+1}} \tag{19}
\end{equation*}
$$

$$
\alpha=\frac{4 \tau\left(S S B_{0} / S P R_{0}\right)}{5 \tau-1} \text { and } \beta=\frac{S S B_{0}(1-\tau)}{5 \tau-1}
$$

where $S S B_{0}$ is unexploited female spawning stock biomass, $S P R_{0}$ is unexploited spawning stock biomass per recruit, $\tau$ is steepness, and $e^{\delta_{y+1}}$ are annual lognormal recruitment deviations..

## Spawning Stock

Female spawning stock biomass in each year is calculated from:

$$
\begin{equation*}
S S B_{y}=\sum_{i=1}^{A} N_{a y} W_{S S B, a} p_{m a t, a} e^{-Z_{a y}(0.5)} \tag{20}
\end{equation*}
$$

where $W_{S S B, a}$ are female spawning stock biomass weights-at-age, $p_{m a t, a}$ is the proportion of mature females-at-age, and $-Z_{a y}(0.5)$ is the proportion of total mortality occurring prior to spawning on July $1^{\text {st }}$.

## Catch

Expected fishery catches are estimated from the Baranov catch equation as:

$$
\begin{equation*}
\hat{C}_{a y f}=N_{a y} F_{a y f} \frac{\left(1-e^{\left.-z_{a y}\right)}\right.}{z_{a y}} \tag{21}
\end{equation*}
$$

Expected age composition of fishery catches are then calculated from $\frac{\hat{C}_{a y f}}{\sum_{a} \hat{c}_{a y f}}$. Expected fishery yields are computed as $\sum_{a} \hat{C}_{a y f} \bar{W}_{a y f}$, where $\bar{W}_{a y f}$ are observed mean catch weights.

## Catch-rates

Expected survey catch-rates are computed from:

$$
\begin{equation*}
\hat{I}_{a y}=q \sum_{a} N_{a y}\left(1-e^{-Z_{a y}(0.5)}\right) v_{a} \tag{22}
\end{equation*}
$$

where $v_{a}$ are survey selectivities, $q$ are the estimated catchability coefficients, and $-Z_{a y}(0.5)$ is the proportion of the total mortality occurring prior to the time of the survey (July $1^{\text {st }}$ midpoint). Survey selectivities are modeled with double logistic functions (equation [14]). Expected survey age composition is then calculated as $\frac{\hat{I}_{a y}}{\sum_{a} \hat{I}_{a y}}$.

## Parameter Estimation

The number of parameters estimated is dependent on the length of the time-series, number of fisheries/selectivity blocks modeled, and the number of abundance indices modeled. Parameters are estimated in log-space and then back transformed. The base model of this assessment was defined with an
age-6 plus group, steepness fixed at 1.0, five fishery selectivity blocks, and three survey selectivity blocks. For the base model, 158 parameters are estimated:

1. 32 selectivity parameters ( 5 blocks for the commercial and recreational fisheries; 3 blocks for the surveys)
2. 78 apical fishing mortality rates ( $\mathrm{F}_{\text {mult }}$ in the initial year and 38 deviations in subsequent years for 2 fisheries)
3. 39 recruitment deviations (1982-2020)
4. 5 initial population abundance deviations (age-2 through 6-plus)
5. 3 catchability coefficients (3 survey IOAs)
6. 1 stock-recruitment parameter $\left(S S B_{0}\right.$; the steepness parameter is fixed at 1.0 for the base run $)$.

The model is fit to the data by minimizing the objective function:

$$
\begin{equation*}
-\ln (L)=\sum_{i} \lambda_{i}\left(-\ln L_{i}\right)+\sum_{j}\left(-\ln L_{j}\right) \tag{23}
\end{equation*}
$$

where $-\ln (L)$ is the entire negative $\log$-likelihood, $\ln L_{i}$ are $\log$-likelihoods of lognormal estimations, $\lambda_{i}$ are user-defined weights applied to lognormal estimations, and $\ln L_{j}$ are $\log$-likelihoods of multinomial estimations.

Negative log-likelihoods with assumed lognormal error are derived (ignoring constants) as:

$$
\begin{equation*}
-\ln \left(L_{i}\right)=\ln (\sigma)+0.5 \sum_{i} \frac{\left[\ln \left(\text { obs }_{i}\right)-\ln \left(\text { pred }_{i}\right)\right]^{2}}{\sigma^{2}} \tag{24}
\end{equation*}
$$

where $o b s_{i}$ and pred $_{i}$ are observed and predicted values; standard deviations $\sigma$ are user-defined CVs as $\sqrt{\ln \left(C V^{2}+1\right)}$.

Negative log-likelihoods with assumed multinomial error are derived (ignoring constants) as:

$$
\begin{equation*}
-\ln \left(L_{j}\right)=-E S S \sum_{i=1}^{A} p_{i} \ln \left(\hat{p}_{i}\right) \tag{25}
\end{equation*}
$$

where $p_{i}$ and $\hat{p}_{i}$ are observed and predicted age composition. Effective sample-sizes $E S S$ are used to create the expected numbers $\hat{n}_{a}$ in each age bin and act as multinomial weighting factors.

### 6.2 Model Assumptions/Inputs

Model assumptions include: 1) the unit stock is adequately defined and closed to migration, 2) observations are unbiased, 3 ) errors are independent and their structures are adequately specified, 4) fishery and survey vulnerabilities are dome-shaped, 5) abundance indices are proportional to absolute abundance, and 6) natural mortality and growth do not vary significantly with time. Lognormal error is
assumed for catches, abundance indices, the stock-recruitment relationship, apical fishing mortalities, selectivity parameters, initial abundance deviations, and catchabilities. Multinomial error is assumed for fishery and survey age compositions.

The base model was defined with an age-6 plus group, steepness fixed at 1.0 , five fishery selectivity blocks, three survey selectivity blocks, and input levels of error and weighting factors as described below. Input levels of error for recreational fishery landings estimates were specified with the corresponding CV's estimated from the LDWF LA Creel survey (2014-2020) and estimates hindcast to the historic MRIP time-series (1982-2013; Table 12). Input levels of error for commercial fishery landings were specified with CV's of 0.1 for years where landings were obtained from NMFS commercial records (1982-1998) and CV's of 0.05 for years where landings were obtained from the LDWF Trip Ticket Program (1999-2020; Table 13). Input levels of error for survey catch-rates were specified with CV's estimated from each IOA standardization (Table 7). Annual recruitment deviations were specified with CV's of 0.5 for all years of the modeled time-series.

Lognormal components included in the objective function were equally weighted (all lambdas=1). Input effective sample sizes (ESS) for estimation of fishery and survey age compositions were specified equally for all years of the time-series (all ESS=200).

### 6.3 Model Results

Objective function components, weighting factors, and likelihood values of the base model are summarized in Table 15.

## Model Fit

The base model provides an overall reasonable fit to the data. Model estimated catches match the observations well (Figure 6); however, in the recreational landings time-series, catches are generally overestimated in earlier years of the time-series and under-estimated in the more recent years prior to 2014. Model estimated survey catch-rates provide acceptable fits to the data, but fail to fit all extremes with a noticeable lack of fit to the catch rates of the 1.0 -inch mesh panel in the most recent years of the timeseries (Figure 7). Patterning of the residuals is also apparent, where catch-rates are generally underestimated in the beginning of each time-series and then over-estimated in later years of each time-series until the beginning of the most recent decade, suggesting a contradiction between data sources (i.e., fishery landings vs. survey catch-rates). Model estimated fishery and survey age compositions provide reasonable fits to the input age proportions (Figures 8-10).

## Selectivities

Estimated fishery and survey selectivities are presented in Figures 11 and 12. Survey estimates indicate full-vulnerability to the 1.0 and 1.25 -inch bar mesh sizes at age- 1 and full-vulnerability to the 1.5 -inch bar mesh size at age-2. Commercial selectivity estimates indicate full-vulnerability at age-2 for each period of consistent regulation. Recreational estimates also indicate full-vulnerability at age-2 for each period of consistent regulation. After the 12 -inch recreational MLL regulation was implemented in 1987, the age-1 recreational selectivity estimate was reduced by approximately $50 \%$

## Abundance, Age Composition, Recruitment, and Spawning Stock

Total stock size and abundance-at-age estimates from the ASAP base model are presented in Table 16. Total stock size has varied considerably over the time-series. Stock size generally increased over the first half of the time-series from 8.8 million females estimated in 1982 to a maximum of 14.0 million females estimated in 2000. After 2000, stock size generally decreased to a minimum of 5.0 million females estimated in 2018. The 2020 estimate of female stock size is 8.7 million females.

The age composition of the stock in the most recent years of the time-series (2015-2020) indicates further age truncation where the proportion of the stock $\geq$ age- $3+$ remains less than 10\%. (Figure 13). The 2019 and 2020 estimates of the proportion of the stock $\geq$ age- $3+$ are the lowest on record ( $5 \%$ and $4 \%$ respectively). The age composition of the stock $\geq$ age- $3+$ varied in earlier years of the time-series prior to 2015, with a maximum of $22 \%$ estimated in 1982, a minimum of $7 \%$ estimated in 1990 , and an average of $13 \%$ from 1982-2014. The age-composition $\geq$ age- $3+$ observed in the landings time-series depicts a similar trend where the lowest estimates on record are the most recent (Figure 13).

Estimates of age-1 recruitment (Figure 14) follow comparable trends with total stock size (Table 16). The average recruitment (geometric mean) over the entire time-series is 6.5 million fish. The average recruitment (geometric mean) in the most recent decade is 5.7 million fish. The 2018 recruitment estimate is the second lowest of the time-series ( 3.7 million female fish). The 2020 age- 1 recruitment estimate is 6.6 million female fish.

Female SSB estimates are presented in Figure 15. Female SSB has also varied considerably over the timeseries. After an initial decline in earlier years of the time-series to a low of 4.3 million pounds estimated in 1989, female SSB generally increased to a maximum of 9.1 million pounds observed in 2008. After 2008, female SSB began to decrease. The most recent SSB estimates of the time-series (2016-2020) are the lowest on record (4.27, 3.0, 2.4, 2.7, and 3.3 million pounds respectively).

Estimated fishing mortality rates are presented in Table 17 (annual apical, average, and age-specific) and Figure 16 (average only). Fishing mortality rates have varied over the time-series with a clear upward trend apparent in the most recent decade. Before 2012, the time-series of average F estimates was relatively flat and generally lacked a trend with a mean of 0.62 per year from 1982-2011. Beginning in 2012, average fishing mortality rates increased to over 0.9 per year and have remained high with a mean of 0.91 per year from 2012-2020. The 2017 estimate of average F is the highest on record ( 1.7 per year). The 2020 estimate of average F is 0.72 per year.

## Stock-Recruitment

No discernable relationship is observed between female SSB and subsequent age-1 recruitment (Figure 17). However, the most recent female SSB estimates are the lowest on record and the 2018 estimate of age- 1 female recruits is the second lowest on record. The ASAP base model was run with steepness fixed at 1.0. The estimated unexploited female SSB was 43.5 million pounds. Alternate runs with steepness values fixed at $0.95,0.90,0.85$, and 0.80 are discussed in the Model Diagnostics Section below.

## Parameter Uncertainty

In the ASAP base model, 158 parameters were estimated. Asymptotic standard errors ( $\pm 2$ ) for the timeseries of age-1 female recruits are presented in Figure 14. Markov Chain Monte Carlo (MCMC) derived confidence intervals (95\%) for the average fishing mortality rate and female SSB time-series are presented in Figures 15 and 16.

### 6.4 Management Benchmarks

Overfishing and overfished limits should be defined for exploitable stocks. The implication is that when biomass falls below a specified limit, there is an unacceptable risk that recruitment will be reduced to undesirable levels. Management actions are needed to avoid approaching this limit and to recover the stock if biomass falls below the limit.

Precautionary limits were proposed in earlier LDWF SST assessments (West et al. 2011, West et al. 2014, West et al. 2019) based on the history of the stock by requiring that female SSB not fall below the lowest level observed in the fishery prior to 2010 in which the stock demonstrated sustainability (i.e., no observed decline in recruitment over a wide range of female SSB; Figure 17). This would be similar to maintaining the stock above a limit spawning potential ratio (SPR; Goodyear, 1993) where SPR is estimated from mature female biomass rather than total egg production. The method for calculating the SPR $_{\text {limit }}$ and the corresponding limit reference points is presented below.

When the stock is in equilibrium, equation [20] can be solved, excluding the year index, for any given exploitation rate as:

$$
\begin{equation*}
\frac{S S B}{R}(F)=\sum_{i=1}^{A} N_{a} p_{m a t, a} W_{S S B, a} e^{-Z_{a}(0.5)} \tag{29}
\end{equation*}
$$

where total mortality at age $Z_{a}$ is computed as $M_{a}+v_{a} \times$ Fmult; vulnerability at age $v_{a}$ is taken by rescaling the current F-at-age estimate (geometric mean 2018-2020) to the maximum. Per recruit abundance-at-age is estimated as $N_{a}=S_{a}$, where survivorship at age is calculated recursively from $S_{a}=$ $S_{a-1} e^{-Z_{a}}, S_{1}=1$. Per recruit catch-at-age is then calculated with the Baranov catch equation [21], excluding the year index. Yield per recruit ( $\mathrm{Y} / \mathrm{R}$ ) is then taken as $\sum_{a} C_{a} \bar{W}_{a}$ where $\bar{W}_{a}$ are current mean fishery weights at age (arithmetic mean 2018-2020). Fishing mortality is averaged by weighting by relative abundance-at-age.

Equilibrium spawning stock biomass $S S B_{e q}$ is calculated by substituting $S S B / R$ estimated from equation [29] into the Beverton-Holt stock recruitment relationship as $\alpha \times S S B / R-\beta$. Equilibrium recruitment $R_{e q}$ and yield $Y_{e q}$ are then taken as $S S B_{e q} \div S S B / R$ and $Y / R \times R_{e q}$. Equilibrium SPR (e.g., $\operatorname{SPR}_{\text {limit }}$ ) is computed as the ratio of $S S B / R$ when $\mathrm{F}>0$ to $S S B / R$ when $\mathrm{F}=0$.

As reference points to guide management, we estimate the spawning potential ratio and average fishing mortality rate that lead to the lowest SSB observed prior to 2010 ( $\mathrm{SSB}_{\text {limit }}, \mathrm{SPR}_{\text {limit }}$ and $\mathrm{F}_{\text {limit }}$ ). The targets of fishing should not be so close to the limits that the limits are exceeded by random variability of the environment. Therefore, we propose a SSB target ( $\mathrm{SSB}_{\text {target }}$ ) as the median SSB prior to 2010 in which the stock demonstrated sustainability and estimate the SPR and average F that lead to this target $\left(\mathrm{SPR}_{\text {target }}\right.$ and $\mathrm{F}_{\text {target }}$.

The proposed limits and targets of fishing are presented in Figure 18 relative to each respective timeseries. Current estimates are taken as the geometric mean of the 2018-2020 estimates.

Also presented are a plot of the stock-recruitment data, equilibrium recruitment, and diagonals from the origin intersecting $R_{e q}$ at the $\mathrm{SSB}_{\text {limit }}, \mathrm{SSB}_{\text {target }}$, and maximum SSB estimates of the time-series, corresponding with a $\mathrm{SPR}_{\mathrm{limit}}$ of $9.8 \%$, a $\mathrm{SPR}_{\text {target }}$ of $14.1 \%$, and a maximum SPR of $20.8 \%$ (Figure 19). Limit and target reference points are also presented in Table 18.

### 6.5 Model Diagnostics

## Sensitivity Analysis

In addition to the base model run, a series of sensitivity runs were used to explore uncertainty in the base model's configuration.

The ASAP base model was run with steepness fixed at 1.0 . Alternate runs were conducted examining reference point estimates with steepness fixed at $0.95,0.90,0.85$ and 0.80 (Models 1-4).

Additional sensitivity runs were conducted by separately up-weighting the contributions of fishery yield and the IOA components within the base models objective function (lambdas increased from 1 to 10; Models 5 and 6).

An additional sensitivity run was conducted by time-varying the baseline M-at-age used in the ASAP base model by adjusting it to the winter severity index presented in Table 5 (Model 7). Baseline M-at-age $\left(M_{a}\right)$ was allowed to vary with time $\left(M_{a, y}\right)$ by adjusting to the winter severity index $\left(W S_{y}\right)$ assuming winter mortality events are additive as:

$$
\begin{equation*}
M_{a, y}=M_{a}+\left(W S_{y} \times c\right) \tag{30}
\end{equation*}
$$

The value of the scaling parameter $(c)$ above was chosen arbitrarily (in this case $c=0.25$ ).
Another sensitivity run was conducted by increasing the discard mortality rate assumption from $10 \%$ to 25\% (Model 8).

An additional sensitivity run was conducted where the ALK's developed from the damped growth model (Table 6) were used to assign ages to the entire time-series of fishery landings (Model 9).

Another sensitivity run was conducted using the MRIP ACAL time-series (see https://www.fisheries.noaa.gov/recreational-fishing-data/recreational-fishing-data-glossary\#calibrateddata), rather than the FCAL time-series, to hindcast LA Creel estimates to the historic MRIP time-series (Model 10). This time-series was developed using the same approach described in Appendix 1 with the ACAL estimates substituted for the FCAL estimates.

Another sensitivity run was conducted using the MRIP size distributions with the FES and APAIS calibrations applied (Model 11).

A final sensitivity run was conducted that included estimates of SST bycatch (females only > age-0) from the LA inshore shrimp fishery (Table 4) as an additional fishery fleet (Model 12).

Results of each sensitivity run relative to the proposed limit reference points are presented in Table 19. Current estimates of female SSB and average F are taken as the geometric mean of the 2018-2020 estimates. Estimates from all sensitivity runs indicate the stock is currently below $\mathrm{SSB}_{\text {limit. }}$. Estimates from all sensitivity runs indicate the fishery is currently operating above $\mathrm{F}_{\text {limit }}$ with the exception of Models 5, 7, and 10. Model 7 (winter-severity index used to time-vary M) resulted in the lowest estimate of current F due to a high M estimated from the severe winter in 2018, but also led to one of the lowest estimates of current SSB of all model runs.

Also presented are estimates of maximum sustainable yield (MSY) and associated reference points for those sensitivity runs with the steepness parameter not fixed at 1 (Table 20). Results of each run indicate that the fishery is currently operating past MSY, where ratios of current F and $\operatorname{SSB}$ to $\mathrm{F}_{\text {MSY }}$ and SSB $_{\text {MSY }}$ are above and below 1 respectively. It's important to note, however, that the selection of specific values for the steepness parameter results in specified values of SSB $_{\text {MSY }}, \mathrm{F}_{\text {MSY }}$, and other MSY statistics. Therefore, MSY values are not estimated per se, but are the results of the value selected for steepness.

## Retrospective Analysis

A retrospective analysis was conducted by sequentially truncating the base model by a year (terminal years 2016-2020). Retrospective estimates of age-1 female recruits, SSB and average fishing mortality differed from the base run (Figure 20). Terminal year estimates of age-1 recruits and female SSB indicate a marginal positive bias, where estimates tend to decrease as more years are added to the model. Terminal year estimates of average fishing mortality rates indicate a larger negative bias, where estimates tend to increase as more years are added to the model.

## 7. Stock Status

The history of the LA SST stock relative to $\mathrm{F} / \mathrm{F}_{\text {limit }}$ and $\mathrm{SSB} / \mathrm{SSB}_{\text {limit }}$ is presented in Figure 21. Fishing mortality rates exceeding $\mathrm{F}_{\text {limit }}\left(\mathrm{F} / \mathrm{F}_{\text {limit }}>1.0\right)$ are defined as overfishing; spawning stock sizes below $\mathrm{SSB}_{\text {limit }}\left(\mathrm{SSB} / \mathrm{SSB}_{\text {limit }}<1.0\right)$ are defined as the overfished condition.

## Overfishing Status

The current estimate of $\mathrm{F} / \mathrm{F}_{\text {limit }}$ is $>1.0$, suggesting the stock is currently undergoing overfishing. The current assessment model also indicates that the stock has been undergoing overfishing since 2012 with the exception of 2014 and the terminal year and also experienced overfishing in a few years earlier in the time-series.

## Overfished Status

The current estimate of $\mathrm{SSB} / \mathrm{SSB}_{\text {limit }}$ is $<1.0$, suggesting the stock is currently in an overfished state. The current assessment model also indicates that the stock has been overfished since 2016. The current SPR estimate is $6.3 \%\left(\mathrm{SPR}_{\text {limit }}=9.8 \%\right)$.

## Control Rules

There is currently no harvest control rule established for the LA SST stock.

## 8. Research and Data Needs

As with any analysis, the accuracy of this assessment is dependent on the accuracy of the information of which it is based. Below we list additional recommendations to improve future assessments of SST in Louisiana.

Assessment of regional or estuarine-specific spotted seatrout populations could differentiate exploitation rates and stock status within the state. If time-series of fine-scale spatial distribution data become available that allow for spatially-explicit assessment, results could be used to determine if regional management is an effective alternative to a statewide management strategy. Current LDWF surveys and commercial landings reported through the LDWF Trip Ticket Program could form the basis for this approach, but the time-series of basin-level recreational harvest and corresponding biological sampling are still not long enough for reliable assessment of regional populations.

Spotted seatrout in south-west LA from the Texas border to the Mermentau River are currently managed with slightly different regulations than the remainder of the state. Again, if data become available that allow for spatially-explicit assessment, results could be used to determine if current management has altered exploitation/stock status in the south-west region and, if so, used as a framework for future management. Current LDWF surveys (LA Creel, fishery-independent, and biological sampling) and commercial landings reporting through trip tickets could form the basis of this approach, but the recreational harvest and biological sampling time-series are still not long enough for reliable assessment of regional populations.

Information describing the connectivity of nearshore and inshore spotted seatrout populations along the Louisiana coast is currently not available. As data becomes available for spatially-explicit assessments, understanding the link between nearshore and inshore populations will become necessary.

The relationship between wetlands losses and the continuation of fishery production within Louisiana has been discussed by numerous authors. Understanding this relationship as it applies to the LA SST stock should be an ongoing priority.

This assessment highlights differing trends between fishery-independent catch-rates and fisherydependent data sources. These differences should be evaluated further to determine which trends are truly reflective of population abundance, or whether other factors (e.g., increasing harvest efficiencies, changing vulnerabilities of the stock, etc.) are involved.

Only limited age data are available from the LDWF marine gillnet survey. Ages of survey catches in this assessment were assigned from ALK's developed from a growth model. Continuing the collection of age
samples directly from the survey would allow a more accurate representation of survey age composition in future assessments.

Winterkill events were included as a sensitivity run in this assessment by time-varying M-at-age proportionally to a winter-severity index. If age-classes are affected disproportionally to cold-stun deaths this approach will introduce bias into model estimates. Investigation of the relationship between spotted seatrout cold-stun deaths and age-class is needed.

Factors that influence year-class strength of spotted seatrout are poorly understood. Investigation of these factors, including inter-annual variation in seasonal factors and the influence of environmental perturbations, could elucidate causes of inter-annual variation in abundance, as well as the species stockrecruitment relationship.

Spawning potential ratio estimates may be biased if egg production does not scale linearly with female body weight. Recent estimates of a LDWF fecundity study suggest fecundity at size and female biomass at size are roughly equivalent; however, error estimates around the fecundity estimates were large due to low sample sizes precluding their use in this assessment update. Current management benchmarks are based on the history of the stock by requiring the stock biomass to not fall below the lowest level observed earlier in the fishery. If management strategy were to change so that benchmarks are based on the reproductive potential of the stock, unbiased estimates of SPR would be needed.

Fishery-dependent data alone is not a reliable source of information to assess status of a fish stock. Consistent fishery-dependent and fishery-independent data sources, in a comprehensive monitoring plan, are essential to understanding the status of fishery. Present monitoring programs should be assessed for adequacy with respect to their ability to evaluate stock status, and modified if deemed necessary.

With the recent trend toward ecosystem-based assessment models (NMFS 2001), more data is needed linking spotted seatrout population dynamics to environmental conditions. The addition of meteorological and physical oceanographic data coupled with food web data may lead to a better understanding of the spotted seatrout stock and its habitat.

## 10. Tables

Table 1: Louisiana annual commercial and recreational spotted seatrout landings (in millions of pounds) derived from NMFS statistical records, LDWF Trip Ticket Program, MRIP, and LA Creel. Recreational landings represent harvest only. Confidential commercial landings records ( ${ }^{(* * *)}$ ) are not presented.

| Year | Harvest |  | \%Commercial | \%Recreational |
| :---: | :---: | :---: | :---: | :---: |
|  | Commercial | Recreational |  |  |
| 1982 | 0.73 | 4.87 | 13.0 | 87.0 |

Table 6: FAO proposed guidelines for indices of productivity for exploited fish species.

| Parameter | Productivity |  | Species |  |  |
| :---: | :---: | :---: | :---: | :---: | :---: |
|  | Low | Medium | High | Spotted Seatrout |  |
| M | $<0.2$ | $0.2-0.5$ | $>0.5$ | 0.3 | Score |
| K | $<0.15$ | $0.15-0.33$ | $>0.33$ | 0.36 | 2 |
| tmat | $>8$ | $3.3-8$ | $<3.3$ | 2 | 3 |
| tmax | $>25$ | $14-25$ | $<14$ | 10 | 3 |
| Examples | orange roughy, many <br> sharks | cod, hake | sardine, <br> anchovy | Spotted Seatrout Productivity Score $=2.75$ <br> (high) |  |

Table 7: Annual sample sizes, nominal proportion of positive samples and nominal CPUEs of positive samples, indices of abundance, and corresponding coefficients of variation derived from the LDWF fishery-independent marine gillnet survey. Nominal CPUE and abundance indices have been normalized to their individual long-term means for comparison.

| Year | 1.0" Mesh |  |  |  |  | 1.25" Mesh |  |  |  |  | 1.5" Mesh |  |  |  |  |

Figure 16: ASAP base model estimated average fishing mortality (MCMC median). Dashed lines represent $95 \%$ MCMC derived confidence intervals.

Figure 17: ASAP base model estimated age-1 recruits and female spawning stock biomass. Arrow represents direction of the time-series. The yellow circle represents the most current data pair (2020 age-1 recruits / 2019 female SSB) and the yellow triangle represents the 2020 SSB estimate. The green circle represents the first data pair (1983 age-1 recruits / 1982 female SSB).

Figure 18: Time-series of ASAP base model estimated average fishing mortality rates, female spawning stock biomass, and spawning potential ratios relative to proposed limit and target reference points. Current values represent the geometric mean of the 2018-2020 estimates.

Figure 19: ASAP base model estimated age-1 recruits and female spawning stock biomass (open circles).
Equilibrium recruitment is represented by the bold horizontal. The yellow circle represents the most current data pair ( 2020 age-1 recruits / 2019 female SSB) and the yellow triangle represents the 2020 SSB estimate. The green circle represents the first data pair (1983 age-1 recruits / 1982 female SSB). Equilibrium recruitment per spawning stock biomass corresponding with the limit and target spawning stock biomass reference point estimates and the maximum spawning stock biomass are represented by the slopes of the dashed diagonals $\left(\mathrm{SSB}_{\text {limit }}=9.8 \% \mathrm{SPR} ; \mathrm{SSB}_{\text {targel }}=14.1 \%\right.$; max. $\mathrm{SSB}=20.8 \% \mathrm{SPR}$ ).

Figure 20: Retrospective analysis of ASAP base model. Top graphics depict annual average fishing mortality and female spawning stock biomass estimates. Bottom graphic depicts estimated age-1 female recruits.

Figure 21: ASAP base model estimated ratios of annual average fishing mortality rates and female spawning stock biomass to the proposed limit reference points ( $\mathrm{F}_{\text {limit }}$ and $\mathrm{SSB}_{\text {limit }}$ ). Also presented are the proposed target reference points (yellow lines). Arrow represents direction of time-series. The first and last year of the time-series are identified along with the years overfishing occurred and/or the stock was considered overfished. The yellow circle represents current status (geometric mean 2018-2020). Bottom graphic depicts current status and results of 2000 MCMC simulations relative to proposed limit and target reference points.

## Appendix 1:

# LA Creel/MRIP Calibration Procedure 

Joe West and Xinan Zhang<br>Office of Fisheries<br>Louisiana Department of Wildlife and Fisheries<br>Updated 10/29/2020

## Overview

The Louisiana Department of Wildlife and Fisheries (LDWF) conducts stock assessments on important recreationally and commercially landed species. Time-series of fishery removals are critical components of these stock assessments as they provide the level of depletion of the resource through time. Beginning in 2014, LDWF started its own creel survey (LA Creel) to provide recreational landings estimates for Louisiana-specific fishery management and stock assessment purposes. Prior to 2014 recreational landings estimates were taken from the National Marine Fisheries Service's Marine Recreational Intercept Program and the earlier Marine Recreational Fisheries Statistical Survey (MRIP/MRFSS). The MRIP and LA Creel surveys were conducted simultaneously in 2015 for benchmarking purposes. Methods are now needed to calibrate MRIP landings estimates to LA Creel landings estimates for species with upcoming LDWF stock assessments.

## Calibration Methodology

A ratio estimator approach is described below allowing hind-casting of LA Creel recreational harvest estimates to 1982. The calibration procedure to hind-cast LA Creel discard estimates is presented in the Appendix of this document.

Concurrent harvest rate estimates of LA Creel and MRIP are only available for the single year (2015) both surveys were conducted simultaneously. Effort estimates, however, are available from both surveys for multiple years (2015-2017). The reliability of this calibration procedure could be greatly improved with more comparison years of the surveys.

Note: MRIP private fishing effort is distributed across the various fishing modes (shore, inshore, and offshore) by applying the observed distribution of those modes from the dockside survey. In 2016 and 2017, the MRIP effort estimation process required additional estimations, as the dockside portion of that survey was not conducted in Louisiana. NOAA Fisheries applied the proportions of trips by fishing mode observed in 2015 to the effort data collected in 2016 and 2017 to obtain estimates of angler trips by fishing mode. While this method is clearly not

```
Abbreviations used in this document:
E - Fishing effort
FM - Fishing mode
        C - charter
        CI - charter inshore
        CO - charter offshore
        P - private
        PI - private inshore (LA Creel)
        PO - private offshore
        PR - private boat (MRIP)
        SH - shore (MRIP)
H - Harvest
HR - Harvest rate
D - Discards
DR - Discard rate
PSE - Percent standard error
R - Ratio
V - Variance
y - Year
w - Bimonthly period
wk - Week of year
```

optimal, it does allow comparison of effort over additional years.
The LA Creel survey provides estimates for four fishing modes (FM): private inshore (PI), private offshore (PO), charter inshore (CI), and charter offshore (CO). The MRIP survey provides estimates for five fishing modes: private boat (PR), shore (SH), PO, CI, and CO. For calibration purposes, LA Creel estimates are transformed into a fifth fishing mode equivalent to the MRIP surveys SH mode by separating the PI mode into PR and SH modes. Additionally, the inshore/offshore fishing modes of each survey are collapsed into overall private $(\mathrm{P})$ and charter ( C ) fishing modes for the species included in this report that support predominantly inshore fisheries.

Fishing effort (E) estimates of the two surveys are calibrated separately by collapsed fishing mode (P and SH only) and bimonthly period (w). Because the charter fishing effort frame used by the LA Creel and MRIP surveys are functionally equivalent, charter fishing effort and corresponding variance estimates of the two surveys are assumed equivalent and not adjusted. Harvest rates and corresponding variance estimates of the MRIP and LA Creel surveys for the species included in this report are also assumed equivalent and not adjusted. Calibrated effort estimates of the shore and private fishing modes are then combined with unadjusted MRIP harvest rate estimates to provide time-series of recreational harvest estimates for species with upcoming LDWF stock assessments as described below.

## Fishing Effort

To allow hind-casting of LA Creel effort estimates to the historic MRIP effort time-series, fishing effort calibration factors are calculated as the ratio of mean fishing effort (2015-2017) from each survey by fishing mode ( P and SH only) and bimonthly period as:

$$
\begin{equation*}
\hat{R}_{E, F M, w}=\frac{\bar{E}_{L A c r e e l, F M, w}}{\bar{E}_{M R I P, F M, w}} \tag{1}
\end{equation*}
$$

Note: MRIP effort estimates in Equation [1] are based on the FES and APAIS methodologies.
Survey-specific mean fishing effort (angler trips) and calibration factors for the P and SH fishing modes by bimonthly period are presented below.

| FM | w | $\bar{E}_{\text {LAcreel }}$ | $\bar{E}_{\text {MRIP }}$ | $\hat{R}_{E}$ |
| :--- | ---: | ---: | ---: | :--- |
| P | 1 | 141,988 | 760,757 | 0.187 |
| P | 2 | 229,436 | 608,036 | 0.377 |
| P | 3 | 425,433 | 908,285 | 0.468 |
| P | 4 | 349,345 | $1,075,253$ | 0.325 |
| P | 5 | 284,077 | 935,917 | 0.304 |
| P | 6 | 277,228 | 806,998 | 0.344 |
| SH | 1 | 50,377 | 753,943 | 0.067 |
| SH | 2 | 80,580 | 642,766 | 0.125 |
| SH | 3 | 151,142 | 897,938 | 0.168 |
| SH | 4 | 73,203 | $1,095,251$ | 0.067 |
| SH | 5 | 105,286 | $1,228,032$ | 0.086 |
| SH | 6 | 64,342 | 950,532 | 0.068 |

The hind-cast LA Creel fishing effort estimates (1982-2013) are then calculated by fishing mode and bimonthly period as:

$$
\begin{equation*}
\hat{E}_{y, w, F M, \hat{R}}=\hat{R}_{E, F M, w} \hat{E}_{y, w, F M, M R I P} \tag{2}
\end{equation*}
$$

Note: MRIP effort estimates in Equation [2] have been calibrated to the FES and APAIS design changes (FCAL).

Variances of the hind-cast LA Creel fishing effort estimates from Equation [2] are approximated by fishing mode and bimonthly period as:

$$
\begin{equation*}
\hat{V}\left(\hat{E}_{y, w, F M, \hat{R}}\right)=\hat{E}_{y, w, F M, M R I P}^{2} \hat{V}\left(\hat{R}_{E, F M, w}\right)+\hat{R}_{E, F M, w}^{2} \hat{V}\left(\hat{E}_{y, w, F M, M R I P}\right)-\hat{V}\left(\hat{R}_{E, F M, w}\right) \hat{V}\left(\hat{E}_{y, w, F M, M R I P}\right) \tag{3}
\end{equation*}
$$

where

$$
\hat{V}\left(\hat{R}_{E, F M, w}\right)=\hat{R}_{E, F M, w}{ }^{2}\left[\frac{\hat{V}\left(\bar{E}_{L A A c r e e l, F M, w}\right)}{\bar{E}_{L A c r e e l, F M, w}{ }^{2}}+\frac{\hat{V}\left(\bar{E}_{M R I P, F M, w}\right)}{\bar{E}_{M R I P, F M, w}{ }^{2}}\right]
$$

## Harvest

The hind-cast LA Creel harvest estimates (1982-2013) by fishing mode (P and SH only) for the species included in this report are then calculated as:

$$
\widehat{H}_{y, F M, \hat{R}}=\sum_{w} \hat{E}_{y, w, F M, \hat{R}} \widehat{H R}_{y, w, F M, M R I P}
$$

Note: MRIP harvest rate estimates in Equation [4] are FCAL estimates and represent A+ B1 landings only.

Variances of the calibrated harvest estimates are then calculated as:

$$
\begin{gather*}
\hat{V}\left(\widehat{H}_{y, F M, \hat{R}}\right)=\sum_{w}\left[\widehat{E}_{y, F M, w, R}^{2} \hat{V}\left(\widehat{H R}_{y, F M, w, M R I P}\right)+\widehat{H R}_{y, F M, w, M R I P}{ }^{2} \hat{V}\left(\widehat{E}_{y, F M, w, \hat{R}}\right)-\right. \\
\left.\hat{V}\left(\widehat{E}_{y, F M, w, \hat{R}}\right) \widehat{V}\left(\widehat{H R}_{y, F M, w, M R I P}\right)\right] \tag{5}
\end{gather*}
$$

Percent standard errors of the calibrated harvest estimates are then calculated as:

$$
\begin{equation*}
\operatorname{PSE}\left(\widehat{H}_{y, F M, \widehat{R}}\right)=100 \times \frac{\sqrt{\hat{V}\left(\widehat{H}_{y, F M, \widehat{R}}\right)}}{\widehat{H}_{y, F M, \widehat{R}}} \tag{6}
\end{equation*}
$$

The MRIP (FCAL) and hind-cast LA Creel harvest estimate time-series and corresponding PSEs by fishing mode for species with upcoming LDWF stock assessments are presented below.

## Appendix

A ratio estimator approach is described below allowing hind-casting of LA Creel recreational discard estimates to 1982. Concurrent discard estimates of the LA Creel and MRIP surveys are not available.

Analogous to the procedure to hind-cast LA Creel harvest estimates, the hind-cast LA Creel effort estimates of the shore and private fishing modes are combined with unadjusted MRIP discard rate estimates to provide time-series of recreational discard estimates for species with upcoming LDWF stock assessments as described below. Discard estimates of the charter fishing mode for the LA Creel and MRIP surveys are assumed equivalent and not adjusted.

## Discards (1982-2013)

The hind-cast LA Creel discard estimates (1982-2013) are calculated by collapsed fishing mode (P and SH only) and bimonthly period as:

$$
\widehat{D}_{y, F M, \hat{R}}=\sum_{w} \widehat{E}_{y, w, F M, \hat{R}} \widehat{D R}_{y, w, F M, M R I P}
$$

Note: MRIP discard rate estimates in Equation [1a] are FCAL estimates and represent B2 landings only. The calibrated effort estimates are taken from Equation [2].

Variances of the calibrated discard estimates from Equation [1a] are then calculated as:

$$
\left.\left.\begin{array}{rl}
\widehat{V}\left(\widehat{D}_{y, F M, \hat{R}}\right)=\sum_{w}\left[\widehat{E}_{y, F M, w, \hat{R}}{ }^{2} \widehat{V}(\widehat{D R}\right. & y, F M, w, M R I P
\end{array}\right)+\widehat{D R}_{y, F M, w, M R I P}{ }^{2} \widehat{V}\left(\widehat{E}_{y, F M, w, \hat{R}}\right)--12 \mathrm{a}\right]
$$

Percent standard errors of the calibrated discard estimates are then calculated as:

$$
\begin{equation*}
\operatorname{PSE}\left(\widehat{D}_{y, F M, \widehat{R}}\right)=100 \times \frac{\sqrt{\hat{V}\left(\widehat{D}_{y, F M, \widehat{R}}\right)}}{\widehat{D}_{y, F M, \overparen{R}}} \tag{3a}
\end{equation*}
$$

## Discards (2014-2016)

Discard estimates of the LA Creel survey are only available from week 19 of 2016 to present. Discard estimates prior to week 19 of 2016 are imputed by fishing mode (P, SH, and C) and week of year (wk) by calculating discard to harvest ratios from the LA Creel estimates from week 19 of 2016 to week 18 of 2017 as:

$$
\begin{equation*}
\widehat{R}_{D / H, F M, w k}=\frac{\widehat{D}_{L A c r e e l, F M, w k}}{\hat{H}_{L A c r e e l, F M, w k}} \tag{4a}
\end{equation*}
$$

The imputed LA Creel discard estimates are then calculated by fishing mode from week 1 of 2014 to week 18 of 2016 as:

$$
\begin{equation*}
\widehat{D}_{y, w k, F M, \hat{R}_{D / H}}=\widehat{R}_{D / H, F M, w k} \widehat{H}_{y, w k, F M, L A c r e e l} \tag{5a}
\end{equation*}
$$

Variances of the imputed LA Creel discard estimates from Equation [5a] are approximated by fishing mode and week of year as:

$$
\begin{aligned}
\hat{V}\left(\widehat{D}_{y, w k, F M, \hat{R}_{D / H}}\right)= & \widehat{H}_{y, w k, F M, L A c r e e l}^{2} \hat{V}\left(\hat{R}_{D / H, F M, w k}\right)+\hat{R}_{D / H, F M, w k}^{2} \hat{V}\left(\widehat{H}_{y, w k, F F, L A c r e e l}\right)- \\
& \hat{V}\left(\widehat{R}_{D / H, F M, w k}\right) \hat{V}\left(\widehat{H}_{y, w k, F M, L A c r e e l}\right) \quad[6 a]
\end{aligned}
$$

where

The MRIP (FCAL) and hind-cast/imputed LA Creel discard estimate annual time-series and corresponding PSEs by fishing mode for species with upcoming LDWF stock assessments are presented below.

## Appendix 2:

Estimates of Spotted Seatrout and Red Drum Bycatch in the Louisiana Menhaden Reduction Fishery
Louisiana Department of Wildlife and Fisheries
Office of Fisheries

## Overview

The Gulf menhaden reduction fishery is the largest commercial fishery operating in the Gulf of Mexico with the majority of landings occurring in Louisiana (LA) waters. Estimates of spotted seatrout (SST) and red drum (RD) incidental bycatch from the menhaden fishery have been requested to allow comparisons of menhaden fishery bycatch in LA waters relative to the directed LA fisheries.

Incidental bycatch has been characterized in the Gulf menhaden fishery from both at-sea and processing plant studies that were reviewed in SEDAR49-DW-04 (Sagarese et al. 2016). The earlier bycatch studies reviewed did not characterize released catches, only the retained portion, limiting their utility for total bycatch estimation. The more recent studies conducted characterized both released and retained catches (Condrey 1994, de Silva and Condrey 1997, Pulver and Scott Denton 2012* as reviewed in Sagarese et al. 2016). Bycatch observations categorized as kept in Pulver and Scott Denton 2012* are considered retained catches.

## Methods

The bycatch information from the Gulf menhaden fishery used in this analysis was limited to the studies where both retained and released catches were reported along with the number of purse-seine sets observed allowing calculation of per set catch rates for SST and RD (Tables 1 and 2). Catch per set observations are summarized across studies (mean, minimum, and maximum) to provide a range of catch rates that are assumed constant through time and representative of catches in LA waters. The most recent study (Pulver and Scott-Denton 2012*) accounted only for bycatch $>50 \mathrm{~cm}$ (19.7 inches) and is excluded from the SST analysis for that reason.

Annual bycatch can be estimated by expanding the catch per set observations from the annual menhaden fishery effort (number of purse-seine sets per year). Annual menhaden fishery effort observations in LA waters are confidential. To avoid issues reporting bycatch estimates developed from confidential observations, fishery effort is estimated for all years included in this analysis (1982-2019, Figure 1) from a linear regression between the currently available annual effort observations (2000-2018) and the corresponding landings in pounds (sets $=1.114 \mathrm{E}-05 *$ landings $+8.247 \mathrm{E}+03, \mathrm{p}=0.01, \mathrm{r}^{2}=0.37$ ).

Time-series of LA spotted seatrout and red drum incidental bycatch from the menhaden fishery (19822019, Table 3) are estimated by summing the product of the retained and released catches per set (mean, minimum, and maximum), the estimated annual LA menhaden fishery effort, and assumed mortality rates of the catches. All retained catches are assumed to die and released SST and RD catches are assumed to have $100 \%$ and $75 \%$ mortality rates respectively. No information is available on the mortality of released SST in the menhaden fishery, and observations of RD dead releases averaged across studies included in this analysis indicates a $45 \%$ mortality rate. That estimate is increased to account for delayed mortality of the live releases that are disoriented or injured.

Bycatch in units of numbers are converted into weight with assumptions of mean weight of the catches. Mean weight of red drum catches are assumed to be 12.6 pounds based on observations of the LDWF nearshore bottom longline survey and 1.44 pounds for SST assuming a 16 -inch mean total length of the catches and applying the conversions in West et al. (2019).

Recreational landings estimates are taken from the LA Creel survey (2014-2019) and estimates hindcast to the historic MRIP time-series (1982-2013, West et al. 2019). Commercial landings are taken from the LDWF Trip Ticket program (1999-2019) and NOAA Fisheries commercial statistical records (1982-1998, NOAA Fisheries 2020).

## Results

Louisiana bycatch estimates (mean, minimum, and maximum) in units of weight are compared to the SST and RD landings from the recreational and commercial LA fisheries (Table 4).

Bycatch estimates of SST relative to the landings of the directed LA fisheries are minimal. Estimates of SST bycatch from the menhaden fishery in units of weight in the most recent decade are all less than one tenth of one percent (maximum $=0.09 \%$, mean $=0.07 \%$, minimum $=0.06 \%$ ) when compared to the landings of the commercial and recreational LA fisheries (Figure 2).

Bycatch estimates of red drum relative to the directed LA fisheries are also minimal but of greater magnitude than SST estimates. Estimates of RD bycatch from the menhaden fishery in units of weight in the most recent decade range from $4.4 \%$ (maximum) to $0.3 \%$ (minimum) with a mean of $2.1 \%$ when compared to the landings of the directed LA fisheries (Figure 3).

Figures

Figure 1: Time-series of estimated LA menhaden fishery effort (number of purse-seine sets per year).

Figure 2: Comparison of LA spotted seatrout commercial and recreational landings, and LA menhaden bycatch estimates for the maximum (top), mean (center), and minimum (bottom) catch per set observations. Values in legends represent the mean landings percentages from 2010-2019.

Figure 3: Comparison of LA red drum commercial and recreational landings, and LA menhaden bycatch estimates for the maximum (top), mean (center), and minimum (bottom) catch per set observations. Values in legends represent the mean landings percentages from 2010-2019.

## Appendix 3:

Evaluation of Commercial Shrimp Fishery Bycatch in Louisiana Waters
Peyton Cagle and Joe West
Office of Fisheries
Louisiana Department of Wildlife and Fisheries
November 2020

## Overview

## Project Need

In 2010, a Fisheries Improvement Project (FIP) was initiated for the commercial shrimp fishery operating in Louisiana (LA) waters as a first step in the process of achieving a sustainability certification for the fishery. This was followed by an official improvement plan for the fishery in 2012. By 2015, the LA shrimp fishery met the goals outlined in the initial plan which allowed the fishery to progress into a comprehensive FIP that addresses all issues within the fishery to ensure the fishery is in compliance with the sustainability standards outlined by the certifying body.

Several action items were outlined in the comprehensive FIP, including the need for current bycatch data from the fishery to assess the main bycatch species per standards of the certifying body. The Louisiana Shrimp Task Force (LSTF) and involved members of the industry approached the Louisiana Department of Wildlife and Fisheries (LDWF) in 2016 and initiated discussions to conduct a study to characterize the current bycatch of the fishery in LA waters. In 2018, LDWF partnered with the LSTF and the American Shrimp Processors Association (ASPA) to fund a one-year observer study designed by the LDWF to focus exclusively on the bycatch of the shrimp fishery operating in LA waters, as the bycatch of the fishery operating in federal waters is monitored and reported by NOAA Fisheries.

## Project Objectives

Objectives of this study were:

1. Characterize the current bycatch of the commercial shrimp fishery operating in LA waters.
2. Identify the main bycatch species of the fishery per standards of the Audubon Nature Institute (ANI) Gulf United for Lasting Fisheries (GULF) Responsible Fisheries Management (RFM) program (ANI 2020).
3. Assess the population resilience of the main bycatch species to fisheries exploitation.

## Fishery Description

The commercial harvest of shrimp in LA dates back to the 1800s (LDWF 2016). As the popularity of shrimp as a food source grew in the early 1900s, the LA commercial shrimp industry expanded and commercial landings began to increase above 20 million pounds annually. Continued expansion of the industry into current times has led to the most valuable commercial fishery operating in LA waters with landings averaging over 70 million pounds annually in the most recent decade.

In the early 1900s, the otter trawl was developed and became the primary fishing gear used by LA shrimp fishers. This was followed by introduction of the butterfly net in the 1950s that allowed stationary fishing in tidal passes. The introduction of skimmer nets in the 1980s, which allowed fishers to focus efforts in shallower water and fish the entire water column, was widely accepted by the LA shrimp fishery.

A shift in gear preference of the LA commercial shrimp fishery has occurred over time as well as an overall decrease in license sales (Table 1). Based on commercial gear license sales, the use of otter trawl and butterfly net gear has decreased since 2000 while the use of skimmer nets has increased. The overall number of commercial licenses sold has decreased by over $70 \%$ since 2000.

Commercial shrimp landings in LA waters and the corresponding number of fishery trips have also decreased since 2000 (Figure 1). Commercial landings have decreased over $30 \%$ since 2000 while the number of fishery trips has declined by over $65 \%$. This disproportionate decrease is primarily due to the characteristics of the shrimp fishery operating in LA waters changing over time, where a noticeable decline occurred in the mid-2000's in the number of trips less than 1-day at sea.

## Regulatory Authority

Regulatory authorities for the LA shrimp fishery are the Governor of Louisiana, the Louisiana Legislature, the Louisiana Wildlife and Fisheries Commission (LWFC), and the Secretary of LDWF. The Governor has the authority to issue executive orders, in limited instances, which are enforced in the same manner as statutes passed by the legislature. The LA Legislature has the authority to enact laws to protect, conserve, and replenish the natural resources of the state, such as gear regulations, licensing requirements, and entry limitations. Some of the authority of the legislature has been delegated to the LWFC, allowing regulatory authority of seasons, quotas, size limits, and possession limits.

Specific to commercial shrimping, the LWFC has the authority to open and close state outside waters, set the inshore shrimp season dates, and modify gear mesh sizes during the special shrimp seasons. The LWFC also has the authority to promulgate regulations regarding the use and configuration of excluder devices. Some authority of the LWFC is delegated to the Secretary of LDWF, including the ability to open or close special and regular shrimp seasons as well as open or close state outside waters.

## Methods

## Bycatch Characterization

In 2019, LDWF, along with the LSTF and ASPA, initiated an observer study of the commercial shrimp fishery operating in Louisiana waters to characterize bycatch of the fishery from July 2019 through June
2020. LGL Ecological Research Associates, Inc. (LGL) was contracted for this study to provide biological staff to act as observers onboard commercial shrimp fishing vessels operating in LA waters.

Fishery participants were solicited though the LSTF, social media, and LDWF news releases, and an online portal was developed for interested commercial fishers to enroll. All commercial fishers operating out of LA ports were eligible to participate in this study. Commercial vessels in which observers were placed were selected randomly from the pool of participating commercial fishers. Commercial fishers randomly drawn from this group were compensated $\$ 350$ per day for each fishing trip where bycatch was observed by an LGL biologist. Fishing trips conducted with observers onboard were not to exceed 48 hours. Trips in which observers were placed were randomly assigned proportional to the recent fishery effort (number of trips) by fishing gear, LDWF Coastal Study Area (CSA), and fishing season (spring, fall, inshore closed).

Bycatch information was collected over the duration of each observed trip by sampling each tow. On vessels containing multiple nets, samples were collected by alternating which net the samples were collected from after each tow. Any observed interactions with sea turtles were to be documented, regardless of which net was sampled.

For each net sampled, the total weight of the tow was estimated through a volumetric approach as described in the NOAA Observer Training Manual (NOAA Fisheries 2010). Multiple fish baskets were equally filled with the entire catch of the sampled tow and then one fish basket was randomly chosen, weighed and used to extrapolate the weight of the entire tow's catch from the number of baskets filled. Catch of the randomly chosen basket was also characterized by sorting, enumerating, and weighing each species to the nearest gram with the exception of white and brown shrimp and jellyfish species where only weight measurements were recorded. The species weight composition of the subsample was then used to extrapolate the total catch weight of each tow.

Size measurements of up to thirty individuals per sampled tow were recorded for penaeid shrimp species and other selected species that are managed or commonly harvested. Large specimens that weren't included in the volumetric sampling method were identified by species, counted, released condition documented, and size or weight measurements recorded when possible. Tow times and locations were also recorded along with the position of the sampled net for each tow.

## Main Bycatch Identification

The ANI GULF RFM program identifies relevant bycatch (non-target catches), whether discarded or retained, as managed non-target species (species regulated for commercial, bait, or recreational use) greater than $1 \%$ of total catch and non-managed non-target species greater than $10 \%$ of total catch (ANI 2020).

## Resilience to Exploitation

Population resilience is a population's ability to withstand perturbation. Populations with higher resilience are at less risk of extinction due to fishery exploitation than populations with lower resilience. Productivity, which is a function of growth rates, fecundity, natural mortality, age at maturity, and
longevity, can be a reasonable proxy for population resilience. Productivity classification indices were developed for each species identified as main bycatch from their life history characteristics based on a classification scheme developed at the Food and Agricultural Organization of the United Nations (FAO) second technical consultation on the suitability of the Convention on International Trade in Endangered Species (CITES) criteria for listing commercially-exploited aquatic species (FAO 2001).

## Results

## Bycatch Characterization

Thirty-three shrimp fishing trips with 363 tows and 501 hours of tow time were observed from July 2019 through June 2020 from 12 individual commercial fishing vessels. Of the twelve participating vessels, 9 fished with skimmer nets, 2 with otter trawls, and 1 with butterfly net gear. The otter trawls were all equipped with bycatch reduction devices (BRDs) and turtle excluder devices, and two-thirds of the skimmer nets were equipped with BRDs.

Observer coverage of the fishery over the course of this study was approximately $0.1 \%$ ( 33 observed trips/37,203 fishery trips) and nearly proportional to the number of fishery trips by gear, CSA, and fishing season with the exception of CSA 6 and 7 due to the lack of fishery participation in those areas (Table 2, Figure 2).

From the 363 observed tows, $14,266 \mathrm{~kg}$ of total catch was observed consisting of 105 unique species or grouped species (Table 3). Four species of penaeid shrimp, 82 finfish species, 12 crustacean species (excluding penaeid shrimp), and 7 non-crustacean invertebrate species were observed. Penaeid shrimp species were the highest group caught by weight ( $48.1 \%$ ), followed by finfish $(40.2 \%)$, crustaceans other than penaeid shrimp ( $5.0 \%$ ), and invertebrates $(3.0 \%)$. Debris made up $3.7 \%$ of the total catch by weight.

The most abundant species caught consisting of $>1 \%$ by weight of the total catch were white shrimp (44.3\%), Gulf menhaden, ( $14.1 \%$ ), Atlantic croaker (5.4\%), blue crab (4.9\%), brown shrimp (3.7\%), spot (3.2\%), jellyfish sp. (2.9\%), sand seatrout (2.8\%), hardhead catfish ( $2.2 \%$ ), gafftopsail catfish ( $2.1 \%$ ), and Atlantic cutlassfish (2.1\%).

The bycatch to shrimp sample ratio error distribution was assumed lognormal and the corresponding sample ratio geometric mean in units of weight was 1.01 (Table 4). Size compositions and mean sizes of penaeid shrimp and the managed and commonly harvested species catches are presented in Table 5 . Catch composition of large specimens not represented in the volumetric samples are presented in Table 6 along with released condition and corresponding size and weight measurements if available. Interactions with diamondback terrapins were observed in which all were released alive (Table 6). No interactions with sea turtles were observed.

## Main Bycatch Identification

Gulf menhaden and blue crab were identified as the main bycatch species of the current LA commercial shrimp fishery per ANI standards. Both are managed species that are greater than $1 \%$ of the total catch by weight. The other non-target species consisting of greater than $1 \%$ of the total catch are non-managed
species not regulated for recreational, bait, or commercial use. No non-managed non-target species was greater than $10 \%$ of the total catch by weight.

## Resilience to Exploitation

Blue crab and Gulf menhaden were assigned productivity/resilience levels (high, medium, or low) based on each species life history characteristics (Table 7). Life history parameter values were taken from the most recent stock assessments if available (SEDAR 2018, West et al. 2019). Parameter values not available in the stock assessment reports were taken from FishBase (Froese and Pauly 2011) and SeaLifeBase (Palomares and Pauly 2020). Parameter values for each of the main bycatch species indicate overall high productivity/resilience.

## Discussion

## Historic Bycatch Ratios

The bycatch to penaeid shrimp sample ratio mean from this study (1.01) is less than an earlier LDWF shrimp bycatch study conducted in LA waters (Adkins 1993). The bycatch to penaeid shrimp sample ratio mean in that study, recalculated as a geometric mean, was 1.24 , suggesting bycatch in the LA shrimp fishery has decreased through time. This decrease is likely due to the changing characteristics of the fishery where skimmer nets have become the preferred gear of the fishery, along with the use of BRDs. An earlier NOAA Fisheries bycatch study conducted in LA waters (Scott-Denton et al. 2006), which only characterized bycatch from the skimmer net fishery operating primarily in Vermilion Bay (CSA 6), reported an overall ratio of bycatch to penaeid shrimp of 0.63.

## Management Implications

For managed species identified as main bycatch, the ANI standards require the effects of the fishery to be considered. Consideration of managed non-target species aims primarily at establishing whether the overall effects of fishing on the stock under consideration and all significant removals are accounted for; and that the management strategy and relative measures are effective in maintaining other managed species from experiencing overfishing and other impacts that are likely to be irreversible or very slowly reversible (ANI 2020).

The main bycatch species of the LA commercial shrimp fishery per ANI standards (Gulf menhaden and blue crab) are regulated species which undergo periodic stock assessments that output estimates used as metrics of stock status (SEDAR 2018, West et al. 2019) with fisheries that currently hold Global Sustainable Seafood Initiative (GSSI) accredited sustainability certifications. Removals of Gulf menhaden and blue crab as bycatch from the LA shrimp fishery have not been considered in the respective stock assessments. Bycatch from the offshore Gulf of Mexico shrimp fishery was considered in the most recent Gulf menhaden stock assessment (SEDAR 2018), but was ultimately not used as a model input by the assessment panelists due to the high uncertainty in the estimated time-series and the relatively insignificant level of bycatch when compared to the landings of the fishery.

Future LDWF blue crab and SEDAR Gulf menhaden stock assessments would be required to consider removals from the LA shrimp fishery per ANI standards. Time-series of bycatch removals could be
estimated directly from annual LA shrimp landings from the mean bycatch to shrimp ratio from this study and the earlier LDWF study (Adkins 1993) along with the percent composition of blue crab and Gulf menhaden in the catches and assumptions of discard mortality. These time-series would unfortunately be considered highly uncertain due to the few bycatch to shrimp ratio estimates available in LA waters over time coupled with the changing characteristics of the fishery, but would allow accurate estimation of the current bycatch removals of the LA shrimp fishery to determine their significance relative to the directed landings of each fishery.

## Appendix 4:

Louisiana Basin-specific Spotted Seatrout Information (2014-2020)<br>Office of Fisheries<br>Louisiana Department of Wildlife and Fisheries

## Overview

The Louisiana spotted seatrout (SST) fishery is one of the largest fisheries operating in Louisiana (LA) waters. Basin-specific SST information has been requested as part of this stock assessment update to allow comparisons of fishery landings and survey catch rates among LA drainage basins.

The Louisiana Department of Wildlife and Fisheries (LDWF) recreational creel survey (LA Creel) estimates fishery effort and fishery catches (harvest + discards) for each LA drainage basin as well as the offshore waters of LA. The LDWF Biological Sampling Program collects size, sex, and age composition information from LA recreational and commercial fishery landings. The LDWF fishery-independent experimental marine gillnet survey collects relative abundance information along with size, sex, and age composition information from important marine species within the LA drainage basins.

Time-series of annual SST basin-specific recreational fishery landings, catch rates of the LDWF fisheryindependent experimental marine gill net survey, and corresponding age compositions are presented in this report from 2014-2020. The basin-specific information presented in this report is derived in the same manner using the same methodology as the statewide metrics presented in the main assessment report. Due to confidentially issues, basin-specific commercial landings are not presented.

## Fishery Information

## Angler Effort, Harvest, and Discards

Annual basin-specific estimates of recreational fishery effort (as angler trips), SST harvest, and SST discards (as numbers of male and female fish) from the LA Creel survey (2014-2020) are presented (Table 1, Figure 1).

Recreational fishery effort varies by LA drainage basin with the majority of angler trips from 2014-2020 occurring in the Pontchartrain, Barataria, and Terrebonne basins ( $24 \%, 29 \%$, and $21 \%$ respectively). Fishing effort in the Vermilion/Teche and Calcasieu/Sabine drainage basins, and the offshore waters of LA accounts for a much smaller fraction of the total LA recreational marine fishing effort ( $6 \%, 15 \%$, and 5\% respectively).

Recreational harvest and discards (2014-2020) also vary with LA drainage basins and follow similar trends with fishery effort with the majority of harvest and discards occurring in the Pontchartrain, Barataria, and Terrebonne basins (harvest: $30 \%, 30 \%$, and $30 \%$ respectively, and discards: $28 \%, 32 \%$, and $34 \%$ respectively). Catches from the Vermilion/Teche and Calcasieu/Sabine drainage basins, and the
offshore waters of LA account for a much smaller percentage of the total LA recreational SST catch (harvest: $2 \%, 8 \%$, and $1 \%$ respectively, and discards: $0.4 \%, 6 \%$, and $0.1 \%$ respectively).

## Female Harvest, Discards, and Age Composition

Annual basin-specific female SST harvest, discards, and corresponding age compositions of female removals (harvest + dead discards) derived from the LA Creel Survey and the LDWF Biological Sampling Program are presented (Table 2, Figure 2) along with the percentage of SST harvest taken by fishing mode (private versus charter). Due to the low SST catches that occur in the offshore waters of LA, offshore female SST landings and age compositions are not presented.

## Pontchartrain Basin (CSA 1)

Female SST recreational harvest estimates in the Pontchartrain basin increased from 1.1 million females harvested in 2014 to 1.5 million females harvested in 2016. After 2016, female harvest decreased to a low of 0.58 million females estimated in 2018. The 2019 and 2020 harvest estimates are 0.69 and 0.84 million females respectively.

Female SST recreational discard estimates in the Pontchartrain basin follow a similar trend as the harvest estimates. Female discard estimates increased from 0.52 million females discarded in 2014 to 0.93 million females discarded in 2016. After 2016, female discards decreased to a low of 0.34 million females estimated in 2018. The 2019 and 2020 discard estimates are 0.35 and 0.59 million females respectively.

The age composition of the Pontchartrain basin female SST removals (harvest + dead discards) from 2014-2020 for age-0 through age-3+ fish are $1.2 \%, 57 \%, 37 \%$, and $4.6 \%$ respectively.

The majority of the Pontchartrain basin female SST harvest (2014-2020) is taken by private anglers (92\%).

## Barataria Basin (CSA 3)

Female SST recreational harvest estimates in the Barataria basin increased from 0.55 million females harvested in 2014 to 1.4 million females harvested in 2016. After 2016, female harvest decreased to 0.62 million females estimated in 2018. The 2019 and 2020 harvest estimates are 1.1 and 0.88 million females respectively.

Female SST recreational discard estimates in the Barataria basin follow a similar trend as the harvest estimates. Female discard estimates increased from 0.61 million females discarded in 2014 to 0.82 million females discarded in 2016. After 2016, female discards decreased to a low of 0.23 million females estimated in 2018. The 2019 and 2020 discard estimates are 0.77 and 0.68 million females respectively. The age composition of the Barataria basin female SST removals (harvest + dead discards) from 20142020 for age-0 through age-3+ fish are $1.5 \%, 65 \%, 29 \%$, and $4.1 \%$ respectively.

The majority of the Barataria basin female SST harvest (2014-2020) is taken by private anglers (83\%).

## Terrebonne Basin (CSA 5)

Female SST recreational harvest estimates in the Terrebonne basin increased from 0.68 million females harvested in 2014 to 1.4 million females harvested in 2017. After 2017, female harvest decreased to 0.89 million females estimated in 2018. The 2019 and 2020 harvest estimates are 0.97 and 1.3 million females respectively.

Female SST recreational discard estimates in the Terrebonne basin follow a similar trend as the harvest estimates. Female discard estimates increased from 0.50 million females discarded in 2014 to 0.81 million females discarded in 2016. After 2016, female discards decreased to a low of 0.32 million females estimated in 2018. The 2019 and 2020 discard estimates are 0.95 and 0.97 million females respectively.

The age composition of the Terrebonne basin female SST removals (harvest + dead discards) from 20142020 for age-0 through age-3+ fish are $1.5 \%, 69 \%, 27 \%$, and $2.6 \%$ respectively.

The majority of the Terrebonne basin female SST harvest (2014-2020) is taken by private anglers (85\%).

## Vermilion/Teche Basins (CSA 6)

Female SST recreational harvest estimates in the Vermilion/Teche basins decreased from 126 thousand females harvested in 2014 to 41 thousand females harvested in 2015. After 2015, female harvest increased to 87 thousand females estimated in 2017. The 2018-2020 harvest estimates are 29, 15, and 65 thousand females respectively.

Female SST recreational discard estimates in the Vermilion/Teche basins follow a similar trend as the harvest estimates. Female discard estimates increased from 6.8 thousand females discarded in 2014 to 11 thousand females discarded in 2015. After 2015, female discards decreased to a low of 5.4 thousand females estimated in 2018. The 2019 and 2020 discard estimates are 8.1 and 8.4 thousand females respectively.

The age composition of the female SST removals (harvest + dead discards) in the Vermilion/Teche basins from 2014-2020 for age-0 through age-3+ fish are $0.41 \%, 73 \%, 22 \%$, and $4.5 \%$ respectively.

The female SST harvest (2014-2020) in the Vermilion/Teche basins is taken almost entirely by private anglers (99.5\%).

## Calcasieu/Sabine Basins (CSA 7)

Female SST recreational harvest estimates in the Calcasieu/Sabine basins increased from 243 thousand females harvested in 2014 to 329 thousand females harvested in 2017. After 2017, female harvest decreased to a low of 127 thousand females estimated in 2018. The 2019 and 2020 harvest estimates are 209 and 260 thousand females respectively.

Female SST recreational discard estimates in the Calcasieu/Sabine basins follow a similar trend as the harvest estimates. Female discard estimates increased from 122 thousand females discarded in 2014 to

153 thousand females discarded in 2015. After 2015, female discards decreased to a low of 64 thousand females estimated in 2018. The 2019 and 2020 discard estimates are 189 and 141 thousand females respectively.

The age composition of the female SST removals (harvest + dead discards) in the Calcasieu/Sabine basins from 2014-2020 for age-0 through age-3+ are $1.2 \%, 64 \%, 29 \%$, and $6.2 \%$ respectively.

The female SST harvest (2014-2020) in the Calcasieu/Sabine basins is taken primarily by private anglers (66\%).

## Fishery-independent Information

Basin-specific female SST indices of abundance and corresponding age compositions of female SST catches from each mesh panel of the LDWF marine experimental gill net survey (1.0-inch, 1.25 -inch, and 1.5 -inch panels only) are presented (Tables 3-5 and Figures 3-5). Each abundance index time-series has been normalized to 1 to facilitate comparisons.

## Pontchartrain Basin (CSA 1)

## 1.0-inch mesh panel

Annual female SST abundance index values estimated from of the 1.0 -inch mesh panel of the Pontchartrain basin gillnet survey increased from 1.0 in 2014 to 1.1 in 2016. After 2016, abundance index values decreased to 0.82 estimated in 2017 and then increased to 1.2 estimated in 2018. The 2019 and 2020 abundance index values are 0.94 and 0.88 .

The age composition of the female SST catches of the 1.0 -inch mesh panel of the Pontchartrain basin gillnet survey from 2014-2020 for age-0 through age-3+ fish are $0.75 \%, 97 \%, 1.6 \%$, and $0.67 \%$ respectively.

### 1.25-inch mesh panel

Annual female SST abundance index values estimated from of the 1.25 -inch mesh panel of the Pontchartrain basin gillnet survey decreased from 0.98 in 2014 to 0.85 in 2015. After 2015, abundance index values increased to 0.97 estimated in 2016 and 1.4 estimated in 2017 and then decreased to 1.1 estimated in 2018. The 2019 and 2020 abundance index values are 0.62 and 1.2

The age composition of the female SST catches of the 1.25 -inch mesh panel of the Pontchartrain basin gillnet survey from 2014-2020 for age-0 through age-3+ fish are $0.25 \%, 97 \%, 11 \%$, and $1.7 \%$ respectively.

## 1.5-inch mesh panel

Annual female SST abundance index values estimated from of the 1.5 -inch mesh panel of the Pontchartrain basin gillnet survey decreased from 0.92 in 2014 to 0.91 in 2015. After 2015, abundance index values increased to 1.3 estimated in 2016 and 1.8 estimated in 2017 and then decreased to 0.62 estimated in 2018. The 2019 and 2020 abundance index values are 0.19 and 1.3.

The age composition of the female SST catches of the 1.5 -inch mesh panel of the Pontchartrain basin gillnet survey from 2014-2020 for age-0 through age-3+ fish are $0 \%, 67 \%, 29 \%$, and $4.4 \%$ respectively.

## Barataria Basin (CSA 3)

## 1.0-inch mesh

Annual female SST abundance index values estimated from of the 1.0-inch mesh panel of the Barataria basin gillnet survey decreased from 0.96 in 2014 to 0.90 in 2015. After 2015, abundance index values increased to 1.2 estimated in 2016 and 2017 and then decreased to 0.71 estimated in 2018. The 2019 and 2020 abundance index values are 1.0 and 1.1.

The age composition of the female SST catches of the 1.0 -inch mesh panel of the Barataria basin gillnet survey from 2014-2020 for age-0 through age-3+ fish are $0.23 \%, 96 \%, 3.0 \%$, and $0.25 \%$ respectively.

### 1.25-inch mesh

Annual female SST abundance index values estimated from of the 1.25 -inch mesh panel of the Barataria basin gillnet survey increased from 0.96 in 2014 to 1.1 in 2015. After 2015, abundance index values decreased to 0.93 estimated in 2016 and then increased to 1.2 estimated in 2017. The 2018-2020 abundance index values are $1.0,0.84$, and 1.0 respectively.

The age composition of the female SST catches of the 1.25 -inch mesh panel of the Barataria basin gillnet survey from 2014-2020 for age-0 through age-3+ fish are $0 \%, 94 \%, 5.9 \%$, and $0.02 \%$ respectively.

## 1.5-inch mesh

Annual female SST abundance index values estimated from of the 1.5 -inch mesh panel of the Barataria basin gillnet survey decreased from 1.4 in 2014 to 0.88 in 2015. After 2015, abundance index values increased to 0.96 estimated in 2016 and 1.6 estimated in 2017 and then decreased to 0.76 estimated in 2018 and 0.50 estimated in 2019. The 2020 abundance index value is 0.92 .

The age composition of the female SST catches of the 1.5 -inch mesh panel of the Barataria basin gillnet survey from 2014-2020 for age- 0 through age- $3+$ fish are $0 \%, 68 \%, 32 \%$, and $0.85 \%$ respectively.

## Terrebonne Basin (CSA 5)

## 1.0-inch mesh

Annual female SST abundance index values estimated from of the 1.0 -inch mesh panel of the Terrebonne basin gillnet survey decreased from 1.2 in 2014 to 0.53 in 2015. After 2015, abundance index values increased to 1.0 estimated in 2016 and 1.1 estimated in 2017 and then decreased to 0.44 estimated in 2018. The 2019 and 2020 abundance index values are 1.1 and 1.6.

The age composition of the female SST catches of the 1.0 -inch mesh panel of the Terrebonne basin gillnet survey from 2014-2020 for age-0 through age-3+ fish are $0.22 \%, 97 \%, 3.1 \%$, and $0.14 \%$ respectively.

### 1.25-inch mesh

Annual female SST abundance index values estimated from of the 1.25 -inch mesh panel of the Terrebonne basin gillnet survey decreased from 1.2 in 2014 to 0.59 in 2015. After 2015, abundance index values increased to 0.72 estimated in 2016 and 1.0 estimated in 2017 and then decreased to 0.88 estimated in 2018 and 2019. The 2020 abundance index value is 1.7.

The age composition of the female SST catches of the 1.25 -inch mesh panel of the Terrebonne basin gillnet survey from 2014-2020 for age-0 through age-3+ fish are $0.11 \%, 91 \%, 8.1 \%$, and $0.59 \%$ respectively.

## 1.5-inch mesh

Annual female SST abundance index values estimated from of the 1.5 -inch mesh panel of the Terrebonne basin gillnet survey decreased from 1.5 in 2014 to 0.86 in 2015 and 0.52 in 2016. After 2016, abundance index values increased to 1.1 estimated in 2017 and then decreased to 0.90 estimated in 2018 and 0.61 estimated in 2019. The 2020 abundance index value is 1.6.

The age composition of the female SST catches of the 1.5 -inch mesh panel of the Terrebonne basin gillnet survey from 2014-2020 for age-0 through age-3+ fish are $0.68 \%, 62 \%, 35 \%$, and $1.8 \%$ respectively.

## Vermilion/Teche Basins (CSA 6)

## 1.0-inch mesh

Annual female SST abundance index values estimated from of the 1.0 -inch mesh panel of the Vermilion/Teche basins gillnet survey decreased from 1.6 in 2014 to 0.51 in 2015. After 2015, abundance index values increased to 1.4 estimated in 2016 and then decreased to 1.0 estimated in 2017. The 20182020 abundance index values are $0.54,0.70$, and 1.2 respectively.

The age composition of the female SST catches of the 1.0 -inch mesh panel of the Vermilion/Teche basins gillnet survey from 2014-2020 for age-0 through age-3+ fish are $0.58 \%, 89 \%, 9.1 \%$, and $1.2 \%$ respectively.

### 1.25-inch mesh

Annual female SST abundance index values estimated from of the 1.25 -inch mesh panel of the Vermilion/Teche basins gillnet survey decreased from 1.2 in 2014 to 0.80 in 2015. After 2015, abundance index values increased to 1.5 estimated in 2016 and then decreased to 1.0 estimated in 2017 and 0.85 estimated in 2018. The 2019 and 2020 abundance index values are 0.73 and 0.91 .

The age composition of the female SST catches of the 1.25 -inch mesh panel of the Vermilion/Teche basins gillnet survey from 2014-2020 for age-0 through age-3+ fish are $0 \%, 84 \%, 15 \%$, and $0.90 \%$ respectively.

## 1.5-inch mesh

Annual female SST abundance index values estimated from of the 1.5 -inch mesh panel of the Vermilion/Teche basins gillnet survey decreased from 1.3 in 2014 to 0.93 in 2015 and 0.75 in 2016. After

2016, abundance index values increased to 1.4 estimated in 2017 and then decreased to 1.2 estimated in 2018 and 0.55 estimated in 2019. The 2020 abundance index value is 0.91 .

The age composition of the female SST catches of the 1.5 -inch mesh panel of the Vermilion/Teche basins gillnet survey from 2014-2020 for age-0 through age-3+ fish are $0 \%, 35 \%, 61 \%$, and $3.8 \%$ respectively.

## Calcasieu/Sabine Basins (CSA 7)

## 1.0-inch mesh

Annual female SST abundance index values estimated from of the 1.0 -inch mesh panel of the Calcasieu/Sabine basins gillnet survey decreased from 1.7 in 2014 to 0.88 in 2015. After 2015, abundance index values increased to 1.0 estimated in 2016 and then decreased to 0.75 estimated in 2017 and 0.46 estimated in 2018. The 2019 and 2020 abundance index values are 0.92 and 1.3.

The age composition of the female SST catches of the 1.0 -inch mesh panel of the Calcasieu/Sabine basins gillnet survey from 2014-2020 for age-0 through age-3+ fish are $0 \%, 80 \%, 8.0 \%$, and $12 \%$ respectively.

### 1.25-inch mesh

Annual female SST abundance index values estimated from of the 1.25 -inch mesh panel of the Calcasieu/Sabine basins gillnet survey decreased from 1.9 in 2014 to 0.84 in 2015. After 2015, abundance index values increased to 1.3 estimated in 2016 and then decreased to 0.75 estimated in 2017. The 20182020 abundance index values are $0.78,0.67$, and 0.79 respectively.

The age composition of the female SST catches of the 1.25 -inch mesh panel of the Calcasieu/Sabine basins gillnet survey from 2014-2020 for age-0 through age-3+ fish are 0\%, 77\%, 20\%, and 3.5\% respectively.

## 1.5-inch mesh

Annual female SST abundance index values estimated from of the 1.5 -inch mesh panel of the Calcasieu/Sabine basins gillnet survey decreased from 1.5 in 2014 to 0.77 in 2015. After 2015, abundance index values increased to 1.9 estimated in 2016 and then decreased to 0.80 estimated in 2017 and 0.67 estimated in 2018. The 2019 and 2020 abundance index values are 0.53 and 0.83 .

The age composition of the female SST catches of the 1.5 -inch mesh panel of the Calcasieu/Sabine basins gillnet survey from 2014-2020 for age-0 through age-3+ fish are $0 \%, 49 \%, 44 \%$, and $8.1 \%$ respectively.

## Tables:

Table 1: Annual basin-specific recreational fishing effort estimates (angler trips; top table), spotted seatrout harvest estimates (numbers of male and female fish; center table), and spotted seatrout discard estimates (numbers of male and female fish; bottom table). CSA 1 represents Pontchartrain basin, CSA 3 represents Barataria basin, CSA 5 represents Terrebonne basin, CSA 6 represents Vermilion/Teche basins, and CSA 7 represents Calcasieu/Sabine basins.

Marine Recreational Fishery Effort (number of angler trips):

| Year | CSA 1 | CSA 3 | CSA 5 | CSA 6 | CSA 7 | Offshore | Totals |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| 2014 | 552,802 | 516,139 | 456,942 | 167,240 | 362,330 | 171,407 | $2,226,861$ |
| 2015 | 584,987 | 716,714 | 452,291 | 138,546 | 393,296 | 140,459 | $2,426,292$ |
| 2016 | 582,157 | 645,427 | 466,906 | 114,261 | 303,086 | 130,749 | $2,242,586$ |
| 2017 | 532,832 | 697,968 | 446,958 | 179,957 | 347,370 | 100,985 | $2,306,069$ |
| 2018 | 479,491 | 690,331 | 556,088 | 125,831 | 315,884 | 108,316 | $2,275,941$ |
| 2019 | 490,411 | 638,076 | 480,277 | 93,897 | 293,421 | 112,381 | $2,108,462$ |

## Figures:

Figure 1: Annual basin-specific recreational fishing effort estimates (angler trips; top graphic), spotted seatrout harvest estimates (numbers of male and female fish; center graphic), and spotted seatrout discard estimates (numbers of male and female fish; bottom graphic). Values in legends represent the mean percentages of the time series (2014-2020).

Pontchartrain (CSA 1):

Barataria (CSA 3):

Terrebonne (CSA 5):

Figure 2: Annual basin-specific female spotted seatrout recreational catch estimates (harvest and discards) as numbers of fish, and the age composition of female landings (harvest + dead discards).
